Lumleian Lectures

ENTITLED

A MEDICAL REVIEW OF THE SURGERY OF THE CHEST.

Delivered before the Royal College of Physicians of London

BY R. A. YOUNG, C.B.E., M.D., B.Sc. LOND.,
LLOW OF THE COLLEGE; SENIOR PHYSICIAN TO THE MIDDLESEX
HOSPITAL; PHYSICIAN TO THE BROMPTON HOSPITAL FOR
CONSUMPTION AND DISEASES OF THE CHEST.

LECTURE II.*

(Delivered on March 21st, 1929.)

THE surgeon and the bronchoscopist seem destined take an increasing share in the treatment of severe lmonary disease. This is more particularly to be pected in cases where medical measures are applicable, where they have failed, or where they quire surgical aid to promote their actions. Some of the most striking applications of surgery this department of medicine have occurred in nnexion with pulmonary tuberculosis, and it will erefore be convenient to deal with these first.

SURGERY IN PULMONARY TUBERCULOSIS.

The earlier applications of surgery in this disease ere chiefly directed to the drainage of cavities and o removal of diseased areas of lung. To some of ese I have referred in my first lecture. They were urageous attempts, but though successes were corded, they did not lead to advances because they alt with effects and failed to influence the primary sease and its spread. They were pioneer efforts, d the historical surveys given by Stephen Paget i d by Rickman Godlee[2] make interesting reading. few chest surgeons are even now in certain cases vising drainage of some cavities which fail to close collapse methods.

Modern surgical methods in this disease are the tcome of the combined experience obtained by rgeons in the treatment of chronic empyema and at of physicians in the use of artificial pneumo-orax as a therapeutic measure. Although these have ogressed practically concurrently, thoracoplasty in ipyema antedated collapse treatment in tubercu-is. To Ludolph Brauer and Lucius Spengler belongs d credit of correlating the two methods. The story of collapse treatment has been admirably scribed by Clive Riviere,[3] Morriston Davies,[4] and exander.[5] Only a brief review is here necessary order to point out the way in which the present actice has been developed. The untimely death Clive Riviere is deeply to be deplored. In this untry the application of combined medical and rgical treatment owes much to his clear and critical iblications, his careful and considered application these methods, and his wide experience of them. y own indebtedness to his writings will be apparent.

After Carson's original suggestion the idea lapsed, d its eventual realisation succeeded only after ow and gradual groping. Houghton, in 1832, noted e beneficial effects of spontaneous pneumothorax an advanced case of phthisis. Stokes, in 1837, rites as if this were a well-recognised sequence. oussaint, a pupil of Potain's, stressed, in 1880, the nprovement after spontaneous pulmonary collapse. n 1884 Potain[6] himself replaced an effusion with erilised air, the first gas replacement on record. le used a manometer to control the pressure, and in 888 recorded two other cases in addition. Meanhile, in 1882, Forlanini had suggested artificial neumothorax as a form of treatment of pulmonary uberculosis, though he seems to have waited until 1888 before actually trying it, and delayed publication of his results until 1894–95. Cayley's attempt to stop hæmoptysis by open pneumothorax took place in 1885. Forlanini and Potain seem therefore to be the first successful pioneers of practical artificial pneumothorax methods. J. B. Murphy[7] in 1895, independently applied this method of collapse treatment, and by 1901 his pupil, Lemke, was able to record 53 cases. Schell, of Indiana, in 1899, was the first after Cayley to apply the method deliberately to the treatment of hæmoptysis. A noteworthy advance was the addition of a water manometer to the apparatus by Saugman in 1904. The adoption of the method in Germany by Brauer was also to prove fruitful. He reported his cases in 1905–06. The credit of introducing the method into England is due to Colebrook, Lillingston, Pearson, and Rhodes in 1911. Although this country was late in the field, and the general adoption of this method as a routine treatment for selected cases was tardy, a great deal of useful work has been done and good results have been obtained. Dr. Clive Riviere's[8] book and the report to the Medical Research Council of Dr. Burrell[9] and Dr. MacNalty have both helped to this end in great measure.

The surgical attempts to induce collapse started even before the medical. Estlander,[10] in 1879, introduced his method of endeavouring to close chronic empyema cavities, and applied the name of thoracoplasty to it. Schede introduced the method of large lateral resections for the same purpose. The first actually to apply this principle to the tuberculous lung was de Cerenville,[11] of Lausanne, in 1885. He removed parts of the upper ribs in four cases with excavation, at the same time draining the cavity in two of them. He therefore slightly antedates the practical application of artificial pneumothorax, though not Potain's gas replacement. He was followed in this operation by Quincke, who, in 1896, advised its use in cases without excavation. Meanwhile Spengler applied the same method to cases with pleural effusion and applied the name of "extra-pleural thoracoplasty." He employed a periscapular incision and his rib resections were more extensive. Garré and Quincke, in 1903 and 1905, suggested thoracoplasty, with or without pneumolysis, for hæmoptysis. It soon became apparent that the resections carried out by these surgeons were not extensive enough. To the physician, Brauer, is due the credit of recognising that if thoracoplasty were to be of value as a supplement to, or substitute for, artificial pneumothorax, it was necessary that sufficient lengths of the ribs should be removed to secure a degree of collapse approaching that obtained by it. The outcome of this was the Brauer-Friedrich operation, carried out by a large horseshoe-shaped incision similar to that of the Schede operation for empyema. This was first performed by Friedrich for Brauer[12] in 1907. Lengths varying from 10–25 cm. were removed from all the ribs from the second to the ninth. In later operations parts of the first rib and of the tenth were also removed. This extensive decostalisation proved dangerous from the shock involved, and disappointing in its effects, since "flutter" of both the mediastinum and of the chest wall sometimes resulted, the operation thus failing to keep the affected side at rest and impeding the effective ventilation of the sound side. Aspiration pneumonia frequently resulted, and there was a very high mortality. Alexander, to whose interesting account of the history I am much indebted, points out the remarkable experimental work done by Gourdet,[13] in 1895, after an operation performed by Boiffin for empyema in 1894. Gourdet demonstrated the much greater effects in diminishing the size of the hemithorax, of removal of parts of the ribs posteriorly, especially if the removal extended to the transverse process of the vertebræ. This mode of removal is generally referred to as paravertebral.

It was not until 1911 that the results of this imp[illegible]ant experimental work were applied [illegible] of thoracoplasty. In [illegible] Wilm[illegible] ...

* Lecture I. appeared in THE LANCET of March 23rd, 1929.

ious danger of cutting through a piece of lung wn out into an adhesion, thus leading sometimes pyopneumothorax. Simple pleural effusion and cutaneous emphysema are also not infrequent nplications, though less serious. In my opinion, s operation, ingenious as it is, has only a limited fulness. Morriston Davies at one time cut hesions by means of a tenotome introduced through intercostal space, the section being controlled by ray observation, but now uses Jacobaeus's method. e third method which has been suggested is by en thoracotomy—the operation being called open rapleural pneumolysis. This is now rarely carried t, as it also involves the risks of effusion and pyema.

Extrapleural Pneumolysis.

In view of the ease with which the parietal pleura n be stripped from the chest wall, it is not sursing that this method has been proposed to permit ther collapse. It was first attempted by Tuffier,[21] 1891, as a preparation for resection of part of the g. Schlange, in 1907, performed a similar operation d filled up the space between the chest wall and the x with iodoform gauze. Tuffier, in 1910, used as a filling. Since that time various substances ve been used to fill up the gap and exert pressure on the lung. Among these may be mentioned afts of fat, muscle, and breast. Paraffin has been ed and sometimes with success.

Attempts have also been made to keep up an trapleural closed pneumothorax. Although these erations are theoretically admirable, their results usually disappointing. It is often difficult to a living filling sufficiently large to accomplish the ject desired. Non-living fillings like paraffin are ble to lead to inflammatory effusion and then to trude. This operation is most often carried out the apex, when it is called apicolysis.

Phrenic Evulsion or Exairesis.

The credit of introducing the principle of paralysing e phrenic nerve in order to allow the diaphragm encroach on the thoracic space with a view to sisting collapse belongs to Stuertz,[22] who, in 1911, oposed and carried out this operation for tuberlosis and bronchiectasis. Sauerbruch at the same ne carried out a similar operation independently. e results were found to be disappointing until, 1922, Willy Felix [23] investigated the anatomy of is nerve in detail. It was then found that it was tremely variable. It is often duplicated in the ck, and occasionally arises in three separate unks. It receives fibres from other nerves, including e nerve to the subclavius muscle, the hypoglossal, e spinal accessory, vagus, and sympathetic. Felix, the suggestion of Thiersch, first carried out the eration of evulsion or exairesis. The nerve is posed in the neck under local anæsthesia and vided. The distal end is slowly twisted round the rceps, and as much as possible is drawn out. Somemes the nerve and its branches can be drawn out most entire, at others only a short length can be vured. The amount removed varies from 3 to or even 18 inches. Although it would appear at the diaphragmatic excursions are a minor ctor in pulmonary ventilation, being responsible nly for one-sixth to one-eighth of the vital capacity, ralysis of one side of the diaphragm allows of nsiderable ascent of that structure into the thorax.

This operation is proving to be of very real value n a variety of conditions. These are clearly tabuted in two excellent papers by Morriston Davies.[24] some cases of active basal tuberculosis, it turns e scale in favour of arrest. In extensive unilateral sease it may exert a favourable influence. As an cessory to artificial pneumothorax it has a wide ld of utility. It can supplement an incomplete neumothorax and render it effective. It can be sed to check the pleural effusions which so frequently ccur in the course of pneumothorax treatment, and t may assist in increasing the period between refills. In cases where the lung fails to expand when artificial pneumothorax is terminated, it may help to close the space left, though thoracoplasty may be necessary to complete the obliteration. It may be a very valuable addition to thoracoplasty. Sauerbruch carries it out beforehand as a test of the capacity of the sound lung to stand the strain imposed by the major operation. It is my almost invariable practice to have this operation done before thoracoplasty since, in a few cases, it may render this unnecessary, and I like to give the patient this chance. It is often of use in alleviating distressing symptoms, such as vomiting after cough, hiccough, and the drag on the heart from marked displacement due to fibrosis. The risks of the operation are slight. Great care should be taken to identify the nerve, as on four recorded occasions the vagus has been cut instead, with fatal result in each case.

Obliterative Pneumothorax.

Another cause of failure in artificial pneumothorax is rapid spread of adhesion between the visceral and parietal pleura. Oleothorax, which will be described in connexion with pleural disease, promises to be of use in preventing this.

ABSCESS AND GANGRENE OF THE LUNG.

Intrapulmonary suppuration results from such a variety of causes that it is not surprising that its causation and treatment are both the subject of considerable controversy. At the outset it is well to exclude bronchiectatic collections, although the two conditions are often associated, since abscess may lead to bronchiectasis and bronchiectasis may cause definite abscess formation. Theoretically, interlobar empyema has also to be distinguished from lung abscess, but the distinction is often only possible at operation.

The classification of cases of abscess and gangrene is also a difficult task. The two conditions can with difficulty be distinguished clinically, and are often associated together. In gangrene there is a larger degree of putrefactive necrosis and greater fœtor with a larger proportion of anaerobic organisms. Recent researches suggest that in many cases they are only degrees or varieties of the same infective process, and that the important factors determining the onset of gangrene are the increased virulence of the organisms or the diminished resistance of the individual. Pressure by growth or aneurysm on a large branch of the pulmonary artery may also determine the development of gangrene. A tentative working classification is: (1) Cases originating in the bronchi. These are chiefly due to aspiration of infected material, either in association with inhaled foreign body or during unconsciousness from anæsthesia or other causes. (2) Parenchymatous. These are often single and may follow pneumonia or other infective processes. This condition is referred to as a "pneumonitis" by some American authors. At the same time, it should be recognised that it is rare in pneumococcus pneumonia apart from secondary infection by pyogenic organisms. (3) Embolic. These are often multiple and may be associated with septicæmia or right-sided infective endocarditis, or with local septic conditions at a distance—e.g., otitis media, appendicitis, or infective thrombo-phlebitis.

The striking feature brought out by some American statistics is the frequency of pulmonary abscess after tonsillectomy, and its association with oral and nasal sepsis. In 105 cases studied by Lilienthal, pneumonia (including influenza) was given as the cause in 29, tonsillectomy in 21. Whittemore [25] found 61 per cent. of 86 cases of abscess preceded by operation on the upper respiratory tract. Wessler [26] states that 28 per cent. of all cases of lung suppuration examined in the X ray department of the Mount Sinai Hospital, New York, arose after operations on the mouth, tonsils, or pharynx. Frederick Moore says the pulmonary abscess occurs once in every 3000 tonsillectomies. There is considerable dispute as to

The treatment of gangrene of the lung depends upon the cause. If it is due to actual vascular pressure or occlusion, operation should not be advised. If it can be proved to be fuso-spirochætal in origin, arsenical injections can be tried. In circumscribed gangrene surgical methods offer the only chance of success.

Tumours of the Lung.

Innocent tumours of the lung are rare, and for the most part they are pathological curiosities. It is only when they cause pressure on the bronchi or on the mediastinal structures that surgical treatment comes under consideration.

Primary malignant tumours of the lung most often commence in the bronchial mucous membrane, and are rarely recognised until they give rise to symptoms from bronchial obstruction or from mediastinal pressure owing to secondary glandular involvement. They are therefore but rarely amenable to surgical removal. There is, however, one form of malignant growth of the lung in which lobectomy is practicable, and in this type it has already given encouraging results. This is that in which the primary growth originates in the lung parenchyma at a distance from the hilum. Lobectomy in a lung which is free from septic infection is an operation with a low mortality, and there is now a definitely evolved technique for its performance. It is surprising how little shock may occur, and remarkable how quickly the parts of the lung left behind can expand to fill the cavity resulting from the excised lung area, unless this is very large, when phrenic evulsion and even partial thoracoplasty may be necessary.

Systematic routine early X ray and bronchoscopic examinations of cases of obscure chest disease, especially those with unexplained, irregular, or suspicious hæmoptysis, are desirable, since if a localised lung growth of this kind can be recognised at an early stage, the patient should be given the chance of an exploratory thoracotomy with a view to lobectomy, if practicable. The outlook in cases of growth of the lung is at present so gloomy that the least chance of improvement should be seized.

Surgery in Bronchial Conditions.

The chief conditions of the bronchi which may be aided by surgical methods are: (1) inhaled foreign bodies, (2) new growths, (3) bronchial fistula, (4) bronchiectasis.

Foreign Bodies.

This question was fully dealt with in the Lumleian Lectures for 1924 by Dr. Thomas McCrae.[33] The pioneer work in the bronchoscopic removal of foreign bodies by Chevalier Jackson has revolutionised the treatment for this accident, to the great advantage of the patients.

Bronchial New Growths.

The bronchoscope has also proved of great value in removing some forms of simple tumour arising in the main bronchi and their chief branches. An interesting paper by Myerson[34] gives a description of a case treated by this means with an analysis of cases recorded by others. Mr. Somerville Hastings[35] has pointed out that a few malignant tumours have been successfully removed through a bronchoscope, while others have been treated by radium introduced or applied by this means. The bronchoscope is proving of increasing value, both in diagnosis and treatment, and its value in both these respects should be more widely recognised in this country.

Bronchial Fistulæ.

These are usually the result of disease or injury of the lung, or of operative procedures used in their treatment. Many of them heal spontaneously, but for others some form of plastic surgery may be necessary. Under certain conditions, notably in bronchiectasis or chronic abscess, they may serve a useful purpose and be retained deliberately.

Bronchiectasis.

Many forms of surgical treatment have been suggested in this disease. Some have already been discarded, and the general results of surgical intervention can hardly be regarded as encouraging, though successes occur which justify operation in selected cases. The ætiology of the condition is so complex that the indications for surgical treatment are difficult to define. Cases which are obviously due to some removable or remediable condition of a bronchus or of the lung tissue in its neighbourhood, such as those described under abscess of the lung and those resulting from inhaled foreign body, are the most likely to benefit. These are often called chronic bronchiectatic abscesses.

Those in which the disease starts early in life are often slowly progressive. In early stages they may be assisted by surgery, but they must be treated before they extend to the opposite side. At present all bilateral cases are inoperable. In cases where there is progressive suppuration leading to destructive changes in the lung tissue around, surgery may be considered, but the risks must be very carefully weighed before a decision is made. The general condition of the patient must also be very thoroughly investigated. Medical measures may in such cases palliate and restore a tolerable state of comfort to the patient, but too often they fail. Bronchoscopic lavage is now proving a valuable adjunct to medical treatment, though it rarely leads to cure. Artificial pneumothorax naturally comes into consideration in unilateral cases. If an efficient collapse of the lower lobe can be obtained, this treatment is worth keeping up, but as a rule it has to be continued indefinitely, since the symptoms usually return when the lung is allowed to expand again. If all these measures fail and the condition of the patient warrants it, surgery may be considered, but only after careful lipiodol investigation. Time should be allowed after this to permit of the expectoration of most of the lipiodol before operation.

The chief surgical operations which have been suggested in the treatment of bronchiectasis are:

1. Draining the cavity by *pneumotomy* as in abscess. This is clearly only suitable where there is a single large cavity. The patient is generally left with a small bronchial fistula, which may eventually close or be closed, though it may be desirable to keep it open.

2. *Ligature* of the branch of the pulmonary artery to the affected lobe was tried in some cases since it leads to fibrosis. This has proved to be of little ultimate value, and is practically no longer employed.

3. *Phrenic evulsion* is worth a trial in basic cases. It helps in the expectoration of the sputum, and in some cases it may lessen or even stop the fœtor. It is also of great value as a preventive of bronchiectasis after abscess of the lung. There is reason to hope that its employment in cases of unresolved pneumonia and other causes of bronchiectasis may prove to be a valuable preventive measure, if the early dilatation is recognised and the operation promptly carried out.

4. *Thoracoplasty.* Rib resections of sufficient extent to cause collapse of the affected lobe or lobes are carried out, usually in stages. Hedblom carries out what he describes as a graded thoracoplasty. A number of successful cases have been recorded in this country, notably by my colleagues, Mr. J. E. H. Roberts[36] and Mr. A. Tudor Edwards.[37] It should be remembered that in many cases the lung tissue is more densely fibrous than in cases of pulmonary tuberculosis, and that the dilated bronchial tubes are not likely to empty and collapse like the vomicæ of that disease. In consequence, the results are on the whole less often satisfying than in tuberculosis, but many patients have been restored to comfort and working capacity.

in 1922 collected 17 cases of cinchophen poisoning, the most prominent symptoms being an urticarial eruption, with or without œdema, albuminuria, fever, headache, malaise, and gastric intestinal disturbances; in two cases there were also cardiac symptoms. He reported symptoms of poisoning even with small doses. Recently 20 cases of jaundice attributed to poisoning by cinchophen have been reported by Worster-Drought [47] and others.[53-62] Omitting one case of which clinical details are not available, and a second [53] attributed to atoquinol, 18 cases of jaundice following the administration of cinchophen have been reported, seven of which were fatal. In three cases the symptoms were those of icterus gravis, and at autopsy the livers showed acute yellow atrophy. From a study of the individual cases it is evident that the symptoms of poisoning occurred after therapeutic doses, except in three cases [57-59] in which considerable doses of cinchophen were taken over long periods without medical supervision; in one of Loewenthal's [62] cases the drug was taken in therapeutic doses, but without medical supervision. Schroeder,[16] however, in a study of the harmful secondary effects of cinchophen, has made no mention of the occurrence of jaundice.

Two fatal cases of acute yellow atrophy after the administration of biloptin have been recorded,[63] [64] and four cases of jaundice which recovered.[63] [65-67] Biloptin, however, being an iodised form of cinchophen, the consideration of these cases does not come within the scope of this paper.

Gastro-intestinal Tract.—Cinchophen, being an acid, causes local irritation and gastric distress in susceptible individuals, or when given in large doses. Hanzlik and others [36] [68] observed toxic symptoms following its administration in very large doses. Absence of gastric distress after doses up to 7 g. daily of neocinchophen (tolysin) was reported by Barbour, Lozinsky, and Clements,[37] and by Chace, Myers, and Killian.[38]

In our experience, using therapeutic doses, symptoms of gastric irritation, varying from a sense of epigastric discomfort to acidity and heartburn, are the commonest expression of intolerance to cinchophen. These symptoms can be controlled in the majority of cases by giving water with the drug, and grs. 15 of sodium bicarbonate; though their presence requires very careful observation of the effect of the drug, it does not necessarily indicate its disuse.

A more marked condition of gastric irritation was seen in a woman aged 66 (Case 4), who suffers from tophaceous gout with recurrent acute attacks. On repeated occasions a single tablet (0·5 g.) has caused symptoms of gastric distress and severe malaise lasting three hours.

Such symptoms as these are likely to prevent anyone from continuing to take the drug, but there are others which are of greater importance, because they are a warning of a toxic effect on the liver and are more insidious in their onset.

Liver.—The first definite symptom of liver poisoning is a loss of appetite. Once its significance is realised there is no mistaking this symptom, for the patient who normally has a good appetite loses it, and develops a distaste for food which is a remarkable and unaccountable experience to him. This symptom was marked in one of our cases: if we had realised its importance immediately and had stopped the drug, the jaundice which subsequently developed could probably have been prevented.

Lethargy and somnolence precede the development of jaundice. Thus in one patient there was unaccountable sleepiness, and she was inclined to fall asleep at any time of the day that she sat down to rest. The symptom was recognised at once as a sign of liver poisoning and the drug was discontinued, but it was too late to prevent the subsequent development of jaundice. Jaundice has been observed in four cases, and it has developed very gradually; it may not appear until a week or two after discontinuing the drug. Associated with jaundice there is considerable malaise, which persists in gradually diminishing degree for a period of months after the jaundice has disappeared.

Three of these cases have already been briefly reported,[54] and the following note is of a more recent case.

CASE 5.—Brewer's drayman, aged 53, was admitted to St. Bartholomew's Hospital on July 15th, 1927, complaining of jaundice. For about 30 years he had suffered from pains in the joints of the feet, and one year before admission he began to have pains in the knees, hips, and hands. Two months before admission he came up to hospital, and the diagnosis of gout was made. He was treated as an out-patient with cinchophen, 0·5 g. three times daily for four successive days of each week. As a result of treatment his pains disappeared, and he was able to walk about unaided, which he could not do previously. Three weeks before admission he felt "out of sorts," and suffered from lassitude, anorexia with occasional vomiting, drowsiness during the day, and insomnia at night. A week later he was seen, and the administration of cinchophen was discontinued immediately. One week before admission jaundice began to appear.

Past History.—Except for his joint trouble he had been previously healthy. There was no history of syphilis. He drank about three pints of beer daily.

Condition on Admission.—The patient was a heavily built man, the skin and sclerotics deeply jaundiced. The temperature was normal. The tongue was furred, and there was considerable dental sepsis. There was a scaly papular rash over the chest and back. The heart and lungs were normal; the blood pressure 130 systolic, 90 diastolic; pulse 60. The liver was palpable about 1 inch below the right costal margin, but there was no tenderness and no ascites. The movements of the hips and ankles were appreciably limited, and there was ankylosis of the metatarsophalangeal joints of both great toes. The urine contained a trace of albumin and a large amount of bile-pigments. Hay's test for bile-salts was negative; red blood cells, 4,880,000; white cells, 15,600; and hæmoglobin, 84 per cent. The van den Bergh reaction direct was strongly positive, indirect 7 units of bilirubin. X ray examination of the stomach revealed nothing abnormal. The glucose-tolerance test was positive, the blood-sugar one hour after the administration of 50 g. of glucose by mouth being 185 mg. per 100 c.cm., and two hours after 170 mg. per 100 c.cm. The urinary diastatic index was 10 units. Blood uric acid 5·3 mg. per 100 c.cm. The Wassermann and Sigma reactions were negative.

Course.—During his stay in hospital the patient developed epigastric pain, which would come on practically every day and last for one or two hours; it was usually relieved by a carminative mixture. The stools were pale, but never clay-coloured. Two weeks after admission his condition improved, and his jaundice began to clear; on August 25th, 1927, he was discharged, the jaundice having almost disappeared, and his liver being barely palpable. Since then he has been under observation and has very gradually recovered his strength.

Kidneys.—Except for the appearance of a transient trace of albumin associated with other severer symptoms of poisoning, we have not observed any signs of renal damage. This agrees with the observations of Barbour, Lozinsky, and others.[3] [37] [38] Hanzlik and others,[36] however, found that cinchophen in the large doses given in the treatment of rheumatic fever (total dosage 4–19 g.) caused albuminuria and sometimes the appearance of casts and white blood cells in the urine of the majority of seven individuals that were observed. Similar findings were reported by Boots and Miller,[68] using neocinchophen.

Skin.—Skin rashes are referred to by other authors, and we have only observed a skin rash in one instance (Case 5).

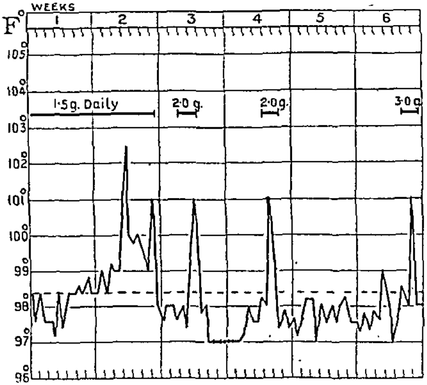
Circulation.—According to Hanzlik [69] small therapeutic doses of cinchophen do not affect the circulation demonstrably except in susceptible individuals, who respond with some acceleration of the pulse and consciousness of the præcordium. Vasomotor depression after therapeutic doses has been observed independently by Barron [70] and Scully.[71]

The following case is an example of cardiovascular disturbance due to cinchophen.

CASE 6.—A man, aged 62, was first seen on Nov. 6th, 1925, recovering from an acute attack of gout in his right foot. He was in good health apart from his gout; he had a clear complexion and a clean tongue; heart and lungs normal; B.P. 160/94; urine normal; there was a family history and past history of gout. Cinchophen with sodium bicarbonate was prescribed. He took cinchophen, 6 g. per week for a period, and then reduced the dose to 5 g.; he continued on this dose until September, 1928, when he was seen again on account of loss of weight (actual loss 9 lb.), dizziness, a feeling of his le giving way as he walked, and of occasional "frightful thumping" in the heart, radiating to the left side of the neck and left temple. His appetite and digestion were good; bowels natural, stools a little pale, and not quite formed; sleep good; no depression. Cinchophen was stopped and sodium bromide in an alkaline mixture was prescribed. Following this treatment his symptoms quickly subsided, and when seen again on Nov. 27th he felt well. Associated with this attack of cardiovascular disturbance attributable, in our opinion, to cinchophen, there was no change in his pulse-rate or diastolic pressure.

Metabolic Effects.—The following case illustrates a somewhat unusual type of cinchophen poisoning, and in this patient the administration of the drug was cautiously persevered with in spite of its toxic effects because of the very definite improvement in the arthritis which resulted from its administration.

CASE 7.—A nurse, aged 43, was admitted to St. Bartholomew's Hospital on Jan. 27th, 1927, complaining of pain and stiffness of both knees. Ten years previously she had had pain in the metacarpophalangeal joints of both hands, followed by pain and stiffness in both shoulders, elbow, and wrist-joints. Six years later she developed similar pain in the right knee and ankle, and one year before admission the left leg and both hips became similarly affected. She had been bedridden for 12 months.



Temperature chart for six weeks in Case 7. The discontinuous line shows the periods during which cinchophen was administered, the daily dose being as stated.

Condition on Admission.—Her general condition was good and there was no clinical evidence of sepsis. There were tenderness and limitation of movement of the shoulder, elbow, wrist, knee- and ankle-joints. There was marked ulnar deviation of the fingers and slight spindle-shaped swelling of the proximal interphalangeal joints. The knee-joints were slightly swollen and fixed at an angle of about 120 degrees. The urine was normal. The blood uric acid was 4·0 mg. per cent. A test-meal showed a trace of free hydrochloric acid. An X ray examination of the affected joints showed absence of cartilage, new bone formation, and areas of bony rarefaction. The diagnosis of gout was made.

Course.—In addition to the application of massage, radiant heat, and extension to the legs, the patient was treated by the oral administration of 0·5 g. of cinchophen three times daily. On the ninth day after the initial dose the proximal interphalangeal and metacarpophalangeal joints of both hands became hot, swollen, and very painful, and on the following day the temperature rose to 102° F. (vide temperature chart attached); there was well-marked general malaise, but the joint pains became less severe. During the next two days the temperature fell gradually to 99°, but rose again the following day to 101°. She suffered from anorexia and nausea, and the cinchophen was discontinued (April 1st).

On April 4th 0·5 g. of cinchophen was given four times during the day, and on the following day the temperature rose to 101° F., but subsided on discontinuing the cinchophen. While taking cinchophen she suffered from nausea, malaise, and general pains. Again on the 13th 2·0 g. of cinchophen were given during the day, followed the next day by pyrexia, nausea, and malaise. On the 25th 1·0 g. of a different preparation of cinchophen was given three times during the day, and she again suffered from nausea, malaise, and a rise of evening temperature, which subsided on the following day, when the drug was discontinued. On May 3rd much smaller doses of cinchophen were given; on this date she received 0·06 g., on the 4th 0·2 g., on the 5th 0·1 g., and on the 6th 0·06 g. The pain in the joints on the 6th was severe. Cinchophen was then discontinued for three days. On the 8th she vomited on two occasions. On the 10th 0·06 g. cinchophen was given once daily for three days and discontinued for three; this was tolerated. On the 16th she received 0·1 g. daily for three days in the same way; on the 17th there was remission of pain, but on the 21st the pain in the left knee was severe, and she experienced a certain amount of nausea. She continued to take 0·1 g. cinchophen daily three successive days of the week, but during the whole of the time while taking it she suffered from nausea and pain in the joints. An attempt to increase the dose of cinchophen to 0·1 g. two or three times daily caused slight malaise, nausea, and a little more pain in the joints, but no fever. On June 22nd she was discharged from hospital with instructions to take 0·06 g. cinchophen twice daily.

The result of this persistent use of cinchophen was a gradual and steady improvement in the arthritis with a temporary setback on each occasion that poisoning symptoms occurred. The ultimate result, however, was very good, and the patient was able to walk out of hospital, though still considerably crippled. Local treatment by massage, radiant heat, and extension applied to both legs contributed to her recovery.

Since her discharge from hospital and after a period of time cinchophen was discontinued and colchicum given in its place. Progress has continued, and she is now able to walk up and down stairs and do a little housework, though her knee-joints are still very stiff.

Idiosyncrasy to Cinchophen.

Several of the cases reported in this communication (Cases 4, 5, and 7) are examples of idiosyncrasy to cinchophen. In one of these (Case 7) cinchophen in small quantities was responsible for an exacerbation of general and joint pains. We have seen this also in a man, aged 66, who has suffered from chronic gout for a number of years.

In his experience cinchophen brings on an attack of acute gout; this sequence of events has happened eight times and is associated with gastric and intestinal disturbance. The patient himself has tried the drug perseveringly, because a single tablet relieves him to some extent of "rheumatic" pains in the thighs. He has tried taking one tablet on alternate days, and also at longer intervals, and has discovered that his maximum tolerance of the drug is one tablet (0·5 g.) taken once a week. His statement of the present position is that he always keeps it by him, and takes one tablet now and then, but he is nervous about using it, because he would rather have chronic pains than an attack of gout.

A familial idiosyncrasy to the drug is suggested by the fact that this man's sister developed jaundice after taking cinchophen.

Two of the cases already reported[54] as having developed jaundice after taking cinchophen are further examples of an idiosyncrasy to the drug; in the one case the symptoms developed after taking only 30 tablets, not more than 10 being taken in one week; in the other there was an idiosyncrasy to two different preparations, and vomiting, followed later by jaundice, occurred after taking only one or at most two 0·5 g. tablets.

Discussion.

The most important toxic effect of cinchophen is on the liver, because when the liver is damaged by cinchophen it is responsible for a severe illness from which recovery is slow. Further, in fatal cases of cinchophen poisoning, death is due to its effect on the liver and to the acute yellow atrophy that results. Yet in spite of the published cases of liver poisoning due to cinchophen Brugsch[72] maintains that there is no question of atophan being a liver poison when given in the usual doses, unless the patient has been on a carbohydrate poor diet and as a result has poor glycogen reserves in the liver. He is indeed so sure of the innocence of atophan as a liver poison that he uses it for the treatment of jaundice in subacute yellow atrophy of the liver, and also in cases in which jaundice is due to a catarrhal cholangitis with blocking of the papilla by a plug of mucus or by congestion of the duct. Weil[73] takes the matter further, and reviews the published cases of liver injury following the administration of atophan; he concludes "that only in the case of England and Holland, and in regard to quite individual cases, are there reports of injury to the liver following on continued use of atophan, while in Germany nothing is known about injury to the liver as a result of the continued administration of atophan." He goes on to say that "the few cases reported from England and Holland of liver disease following on the continued use of atophan are isolated and only have slight scientific foundation."

In view of the cases which we have placed on record in this communication, in some of which atophan was used, and in view of the experience of others recorded in writing, and to which we have given references, the opinions expressed by Brugsch and Weil need modification; and with regard to Weil's statement that nothing is known in Germany about injury to the liver as a result of continued administration of atophan, we feel bound to observe that it was known to the Schering Laboratory in 1924 that patients treated with atophan may "in very rare cases" react pathologically and develop "severe disturbances such as sickness and diarrhœa, *jaundice* and collapse" (the italics are ours).

Conclusions.

There can be no doubt that in cinchophen we have a drug which is often invaluable in the treatment of chronic gout, and in certain cases of this disease a cure can be effected, or great alleviation of symptoms obtained, such as cannot be effected by colchicum or any other means. Toxic symptoms of any severity rarely occur, and by a knowledge of the proper use of the drug we feel that even these can be avoided. At the same time it must be clearly recognised that toxic symptoms due to cinchophen do sometimes occur, and after relatively small doses, in those who have an idiosyncrasy to the drug.

Certain precautions should always be taken in prescribing cinchophen. A small initial dose should be given to test the patient's tolerance of the drug. It is given with water after meals, and if there is any symptom of gastric irritation, it is given with grs. 15 of sodium bicarbonate (cinchophen and sodium bicarbonate cannot be prescribed in the same mixture). It is generally best given, as Graham[9] has advised, on three days in succession each week, but there are occasions in our experience (as in Case 1) in which a smaller dose of cinchophen is more efficient and is well tolerated when distributed throughout the week; that some patients can take the drug continuously is proved by Case 3 in this series. When nutrition is poor and there is a suspicion of poor glycogen reserves in the liver, an ample carbohydrate diet should be given. Finally, any person taking cinchophen must be under medical supervision, and with the appearance of symptoms of liver poisoning, of which we believe a loss of appetite to be the first, the drug should be stopped at once. Case 6 is an example of the fact that toxic symptoms may arise in a patient who has already proved tolerant of the drug for a long time.

THE FORMATION OF SALIVARY CALCULI AND THEIR TREATMENT.

BY CECIL P. G. WAKELEY, F.R.C.S. ENG., F.R.S. EDIN.,

ASSISTANT SURGEON AND LECTURER IN SURGERY, KING'S COLLEGE HOSPITAL; ASSISTANT SURGEON, BELGRAVE HOSPITAL FOR CHILDREN.

CALCULI in the salivary glands are most frequently found between the ages of 20 and 40. Men are affected to a greater extent than women in the proportion of three to one. The size of the calculi varies greatly; they may be as small as grains of sand or as large as a bantam's egg. Thorowgood demonstrated a specimen before the Pathological Society of London which measured 1½ in. in length and 2 in. in circumference. More commonly they vary from the size of a split pea to that of a date-stone. They are usually single and in a small percentage of cases only does recurrence take place after removal. As a rule, calculi in the glandular tissue are spherical or oval, while those in the ducts are elongated and resemble date-stones.

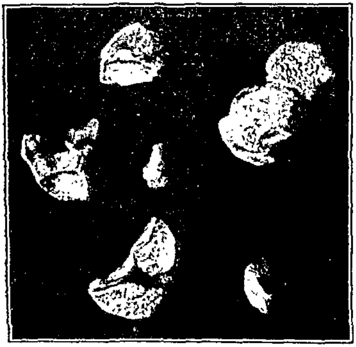
In the ducts they may be multiple and are then usually arranged end to end, the opposed surfaces being faceted. The surface of the calculus may be finely or coarsely granular and is usually of a dirty yellowish-grey colour. The structure varies considerably. In a fair proportion of cases a foreign body has been found as a nucleus. Some calculi are laminated, but in my experience this is rare. By far the majority of stones from the salivary glands and ducts are composed of calcium phosphate and calcium carbonate. A complete analysis of my last 12 cases of submaxillary calculi gives the following composition:—

Calcium carbonate	75·3	per cent.
,, phosphate	10·1	,,
Soluble salts	6·2	,,
Organic matter	6·1	,,
Water	2·3	,,

Ætiology.

The cause of calculus formation in the salivary glands and ducts has been, and still is, the subject of much discussion. That some constitutional condition may predispose to calculus formation seems very improbable. If a general cause was in any way responsible one would expect it to exert its influence upon more than one gland, and to give rise to calculi in several glands or ducts. As a result of carefully examining the very extensive literature on the subject I have been able to discover three cases only in which calculi have been found in more than one gland or duct in the same person. When foreign bodies form the nucleus no doubt they are the initial cause in the formation, as stones in the urinary bladder form round an unabsorbed catgut ligature. Foreign bodies, however, must not be regarded as the sole cause, nor must it be thought that any foreign body introduced into a salivary gland or its duct will of necessity cause the formation of a calculus. The literature abounds with cases in which a foreign body such as a piece of straw, grass, or hair has been lodged in the salivary ducts for long periods of time without giving rise to any calculus formation. Roberg, who investigated 47 cases of salivary calculi between the years 1896 and 1904, is of the opinion that foreign bodies are frequently present in the ducts of the salivary glands without the production of calculi.

FIG. 1.



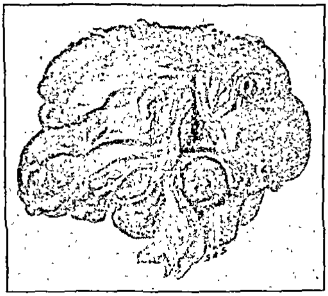
Multiple faceted calculi removed from the submaxillary gland (natural size).

An analysis of the recorded cases of salivary calculi published up to the present time brings out the following figures:—

Submaxillary gland and duct	63·2	per cent.
Parotid gland and duct..	20·6	,,
Sublingual gland and ducts	16·2	,,

It is necessary, therefore, to explain the far greater frequency of calculi in the submaxillary gland and Wharton's duct than in the other salivary glands and their ducts. It must be conceded that, owing to the greater size of the duct and the position of its orifice, foreign bodies such as tartar and particles of food can enter Wharton's duct more easily than they can the ducts of the other salivary glands. The composition of tartar is very *similar to that of calculi.* Therefore, although tartar may quite often be a determining factor, it would be quite impossible to demonstrate it. Similarly, food particles may enter the duct, undergo decomposition there, and simply add to the percentage of organic matter in the calculus without other evidence of their presence.

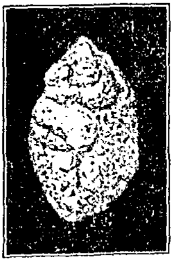
FIG. 2.



Calculus in submaxillary gland (natural size). The gland substance is very much fibrosed and thickened around the calculus.

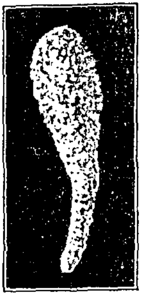
If a salivary calculus is carefully cut through its centre and a culture is made from the interior, bacteria are nearly always found. It might be thought that bacteria were the actual cause of the calculus, but this certainly cannot be the case, since, if infection alone were the important factor, calculi would occur more frequently in the gland and duct which are most often the seat of infection—namely, the parotid and its duct. Bacteria probably do play a part in the formation of calculi by decomposing the proteids in the saliva. It is a well-known fact that if saliva is exposed to the air for a short period of time carbon dioxide escapes

FIG. 3.



Calculus removed from submaxillary gland (one-third larger than natural size).

FIG. 4.



Comma calculus removed from the submaxillary gland and its duct (one-third larger than natural size).

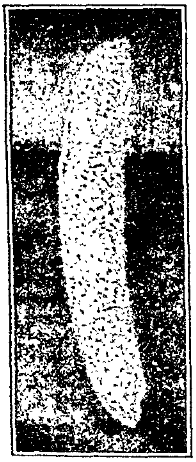
from it and a thin film of calcium carbonate soon forms on the surface. Therefore the removal of carbon dioxide alone is sufficient to precipitate the calcium salts. When bacteria decompose the proteids in saliva ammonia is produced, and probably immediately unites with the carbon dioxide held in solution; thus a condition favourable for calculus formation occurs. If this be so, it is quite reasonable to conclude that bacteria cause, indirectly, a precipitation of the calcium salts of the saliva by increasing the alkalinity of the saliva and removing carbon dioxide.

The composition of the saliva from the submaxillary gland allows easier precipitation of calcium salts than does that of the parotid or sublingual. The factors which predispose to a precipitation of the calcium salts in the submaxillary gland are: (1) high percentage of solids, (2) high percentage of organic matter, (3) greater degree of alkalinity, (4) low content of carbon dioxide.

It is sometimes debated whether the "idiopathic" formation of salivary calculi ever occurs. To me the question appears futile. If by the term "idiopathic" is meant that calculus formation occurs in a perfectly normal secretion in a perfectly normal gland or duct, the answer must clearly be in the negative. On the other hand, it does not seem necessary to postulate the entrance of any gross foreign material, since alterations in the reaction of a system of colloids and inorganic electrolytes are frequently accompanied by precipitation.

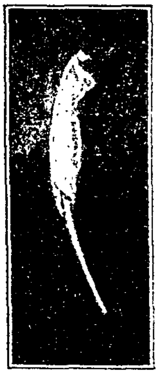
The lamination observed in the precipitation of certain salts in the presence of gels, and known as the Liesegang phenomenon, is profoundly influenced by the reaction of the gel. That variations in hydrogen-ion or hydroxyl-ion concentration in different media can be brought about by bacterial action is too well known to need comment. Hence the introduction of even a single micro-organism and its subsequent multiplication may set up such a disturbance in the equilibrium of an electrolyte-colloid system as to initiate precipitation. How far similar phenomena can be brought about by "filter-passers" is a question which time and experiment alone can solve. It is at any rate of theoretical interest, since these elusive entities are now considered to be important factors in the ætiology of influenzal and various catarrhal conditions. That colloids do play an important part in the formation of salivary calculi is at any rate suggested by their greater frequency in the submaxillary glands, where organic colloid material is present in the greatest abundance.

FIG. 5.



Calculus removed from Wharton's duct (one-third larger than natural size).

FIG. 7.

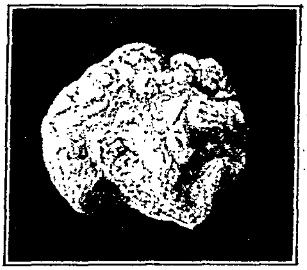


Calculus surrounding a small fish bone. It was removed from Wharton's duct (three times natural size).

Parotid Calculi.

Calculi are very rare in the parotid gland itself, Stenson's duct being much more frequently the seat of the formation. Multiple calculi are more common than single. Noehren, of Buffalo, reported a case in which 14 stones were removed from the parotid duct, and Townsend a case in which four stones were removed. Abscess formation around long-standing calculi is quite a common complication, and should the abscess open externally a fistula results. The masseteric portion of Stenson's duct is the most frequent situation for calculi, and their removal necessitates an external incision. Fistulæ may follow, but are rare if the incision is longitudinal and closed by stitches after the removal of the stones. If calculi be present in the premasseteric portion of the duct they may be liberated by an incision through the buccal mucous membrane.

FIG. 6.



Calculus removed from the orifice of Wharton's duct. It had been in this situation for over six months (one-third larger than natural size).

Submaxillary Calculi.

Calculi found in the submaxillary gland or its duct are usually single (Fig. 1). The single calculus may be seen in a variety of shapes according to the position in which it is lodged, either in the gland or in the duct. If it is in the gland it is usually rounded in appearance (Figs. 2 and 3), while if it is partly in the gland and partly in the duct it assumes a tapering form, the "comma calculus" (Fig. 4), the larger part of the calculus being in the gland while the smaller portion extends into the duct. This type is quite common, and the thinned distal portion is liable to be fractured and may then pass along the duct into the mouth, while the larger proximal portion remains in the gland. Such a calculus in the submaxillary gland cannot be palpated owing to the amount of fibrous tissue surrounding it, but it can nearly always be demonstrated by X rays. If, however, the calculus is in Wharton's duct it is usually moulded by the muscular wall and may be said to form a cast of the duct (Fig. 5). Lastly, if a calculus is formed at the orifice of Wharton's duct, or a small one passes along the duct and becomes impacted there, it is nearly always cylindrical (Fig. 6).

Many examples of calculi surrounding foreign bodies have been described. Perhaps one of the best examples of a specimen in the Royal College of Surgeons' Museum, No. 2234.1 (Fig. 7). It consists of a small fish bone which was found projecting from the orifice of Wharton's duct; it is encrusted with phosphates for more than half its length.

The treatment of submaxillary calculi is quite simple. Calculi in the gland usually necessitate excision of the gland, because there is always considerable fibrosis of the glandular alveoli due to the presence of the calculus and the back pressure exerted thereby. If the stone is in the duct an incision through the mucous membrane of the mouth into the duct is all that is required, and this can easily be performed under local anæsthesia. Calculi may re-form in either the gland or duct after an operation on the duct itself; oral sepsis plays a very important part in such cases. Stricture formation may follow ulceration of the wall of the duct, the ulceration being due either to the calculus or to the incision made in the duct. Incisions within the mouth cavity must always, even in the best circumstances, become infected owing to the innumerable bacteria which are invariably present.

History of a Case.

A man, aged 45, had suffered from chronic enlargement of the right submaxillary gland for three years. He came nder observation in 1922, and a calculus was found at the pening of Wharton's duct and was easily removed. A year ter he returned to the hospital with a swollen submaxillary land, and a calculus was felt in the duct of the gland. he mucous membrane of the floor of the mouth was incised nder local anæsthesia and the calculus removed. An X ray hotograph was taken in order to see if there were any calculi the gland itself, but the result was negative. In 1926 e again presented himself at hospital with a very swollen bmaxillary gland in which a large calculus could be alpated with a finger inside the mouth and the thumb utside. Excision of the submaxillary gland was then ndertaken; three faceted calculi were found inside a very hickened and fibrosed gland, which was practically functionss as far as normal secretion was concerned.

One would expect that owing to their composition alivary calculi would be quite opaque to X rays. his proves to be usually the case, as Harrison, eporting upon 27 cases of salivary calculi in which peration was performed, obtained positive X ray indings in 81·4 per cent.

Calculus formation in the sublingual gland and its uct is a rarity, and very few cases are recorded. owever, calculi are sometimes found in association vith cystic distension of the gland. Burdel has eported a case of stone in the sublingual duct in an nfant three weeks of age.

THE RÔLE OF HYDROCHLORIC ACID IN THE CAUSATION OF GASTRIC PAIN.*

By T. L. HARDY, M.D. Camb., M.R.C.P. Lond.,
ASSISTANT PHYSICIAN, GENERAL HOSPITAL, BIRMINGHAM.

It would seem almost a task of supererogation to revive discussion of an acid factor in the causation of gastric pain, in view of the apparently conclusive observations of Hurst[1] some 20 years ago, observations which have since received confirmation from many sources, clinical and experimental. Nevertheless it cannot be denied that there still exists in the minds of most laymen, and of not a few medical men, the belief that gastric pain must in some way be associated with gastric acidity, a belief which finds its expression in the occasional use of such terms as hyperchlorhydria and acid dyspepsia to denote clinical states illustrating cause and effect, and in the use of sodium bicarbonate or other alkali for their relief. But while the evidence, both clinical and experimental, is definitely opposed to such a view, recent work by Palmer[2] has renewed interest in the subject and certainly demands critical consideration. After confirming Hurst's observations that the mucous membrane of the stomach in healthy individuals was insensitive to concentrations of hydrochloric acid up to 0·5 per cent., he was able to reproduce in ulcer patients under suitable conditions of susceptibility their characteristic pain, not only with 0·5 per cent. hydrochloric acid, but also with concentrations which fell within physiological limits.

The reinjection of the gastric contents obtained at the time of the distress also reproduced it in some instances, and relief was invariably obtained either by emptying the stomach or by the use of alkalis. He found that the pain was produced most readily during the stage of active symptoms, and was usually absent during quiescent periods and after a course of treatment. Further, from a study of 15 cases he found no evidence of a positive response to acid in the absence of an organic lesion of the stomach or duodenum. He finally concluded that hydrochloric acid was not only an adequate stimulus to the pain-producing mechanism of a sensitive peptic ulcer, but was also the stimulus usually in evidence.

It was evident that if these results could be substantiated and the specificity of the test for ulcer established, the clinician would have an additional valuable method of distinguishing gastric pain due to peptic ulcer from that due to distant foci of irritation—for example, in the appendix, the colon, or the gall-bladder. In a later paper Palmer[3] claimed that his methods provided such a test, and the present investigation which follows very much the lines he adopted was undertaken in order to exploit this so-called acid test as an aid in differential diagnosis, and perhaps to throw additional light on the relationship of gastric acidity to gastric pain.

Technique of the Test.

After a night's fast the patient swallows a Ryle's tube and the stomach is emptied of its resting contents. 200 c.cm. of 0·5 per cent. HCl are then introduced into the stomach through the tube. The patient is kept in ignorance of the nature of the injected fluid and is informed that in all probability he will experience no unusual sensation, but that if he does he is to notify the observer. Suitable literature is provided to divert the mind, and at the end of half an hour, if no pain has been complained of, the stomach is emptied and a further 200 c.cm. of acid are introduced, and this is repeated a third time if necessary. The method is substantially that of Palmer, with the slight variation that the stomach is emptied at the end of each half hour period in order to avoid the accumulation of large quantities of fluid and to maintain the concentration of acid at a high level. The test is regarded as positive if the patient complains of unequivocal pain which he is able to recognise as identical with his previous symptoms, identical, that is, in kind, but not necessarily in degree. Severe pain can be promptly relieved by emptying the stomach or by the use of an alkaline powder.

Results of Investigation.

The total number of cases investigated, the great majority of whom attended my out-patient clinic in the first instance, is 228, and the number of examinations carried out 257. They are divisible into two groups—one consisting of 155 cases in whom organic disease of the stomach or duodenum was demonstrable, and the remainder, 73 in number, in whom no local lesion could be discovered. Reliance was placed on X ray diagnosis in 176 cases, severe hæmorrhage in 6, and surgical intervention in 46.

A comparison of the results obtained in the two groups makes it possible to assess the value of the acid test in differential diagnosis.

Table I.—*Organic Diseases of Stomach and Duodenum.*

Diagnosis.	Total cases.	Total tests.	Results of acid test.	
			Pos.	Neg.
Duodenal ulcer	87	105	41	64
Gastric ulcer	50	59	35	24
Gastro-jejunal ulcer	4	4	0	4
Gastric carcinoma	3	3	2	1
Hæmatemesis and melæna ..	6	6	1	5
Gastritis..	7	7	3	4
	157	184	82	102

Table I. shows the results obtained from 184 tests carried out on 157 patients suffering from organic disease of the stomach or duodenum. Eighty-two gave positive tests and 102 negative. Peptic ulcer accounts for the great majority of cases, and it will be noted that the proportion of positive results is considerably higher in ulcers of the lesser curvature than of the duodenum. In three cases of carcinoma two were positive, in one of which the pain was agonising, as was also the case in one of the three positive results in the cases of gastritis. It is interesting to note that the localisation of the pain, though usually referred somewhat vaguely to the epigastrium, may, when at all severe, be exceedingly accurate and even felt in the back. In one case, that of a duodenal ulcer, pain was, curiously enough, felt only in the left axilla; this localisation was reproduced with great accuracy as a result of a positive acid test.

---

* An abstract of this paper was contributed to the discussion on various aspects of gastric chemistry at the Section of Medicine, Royal Society of Medicine, reported on p. 718.

TABLE II.—*Analysis of 103 Cases of Peptic Ulcer.*

Type.	Cases.	Tests.	Acid +.	Symptoms.		Acid —.	Symptoms.	
				Active.	Quiescent.		Active.	Quiescent.
Duodenal	70	88	37	36	1	51	12	39
Gastric	33	41	24	24	0	17	5	12
	103	129	61	60	1	68	17	51

Table II. shows the relationship of the results obtained to the period of the disease in which the test was carried out—whether one of active symptoms or of quiescence. Symptoms were considered to be active when spontaneous pain had been present within the preceding 24 hours. Of the 103 cases that are analysed it will be noted that all the positive results, with one exception, were obtained during a period of active symptoms, but more noteworthy is the occurrence of 17 negative tests during the active period. In one of these, a case of lesser curve ulcer, the symptoms were of recent duration, the pain of unusual intensity, and associated with slight rigidity and a localised area of superficial soreness, so that leakage was suspected.

TABLE III.—*Functional Dyspepsia and Extragastric Lesions.*

Diagnosis.	Total cases.	Total tests.	Results of acid test.	
			Pos.	Neg.
Functional dyspepsia	44	45	4	41
Constipation	12	12	2	10
Chronic appendicitis	7	8	4	4
Chronic cholecystitis	5	5	4	1
Cirrhosis of liver	1	1	—	1
Pancreatitis	1	1	—	1
Adhesions	1	1	—	1
	71	73	14	59

Table III. shows the results obtained in 71 cases where a lesion of the gastric mucosa could be excluded. Forty-four were cases of simple functional disturbance with negative X ray picture, and the remainder examples of gastralgia produced by irritative foci acting at a distance. The 12 cases of appendicitis and cholecystitis were confirmed by operation and the stomach and duodenum found normal in each instance. Nevertheless, four out of seven cases of appendicitis, and four out of five of cholecystitis gave positive acid tests, the pain in the latter being severe and in one case of appendicitis exceptionally so.

Thirty-four cases of ulcer were submitted to operation, and I have to thank my surgical colleague, Mr. H. H. Sampson, under whom the patients were admitted, for permission to make use of this material from which it is possible to obtain a clearer conception of the state of the ulcer in relation to the acid response. The acid test was found to be negative in 20 cases in whom little or no evidence of healing was observed at the operation.

As regards the results of treatment, 24 cases of ulcer with positive results were examined at the end of a course of medical treatment. In all but one the test was negative, and that was a case of a large active ulcer associated with an hour-glass constriction of the stomach. How soon the test becomes negative I am not prepared to say, but I have found it so a week from the commencement of treatment. One test was carried out a week after gastro-jejunostomy and was found to be negative, and a negative result was present a week after removal of the appendix; in both cases the test had previously been positive.

Discussion.

As a result of this investigation I have attempted to supply answers in part or in whole to two questions: (1) Is there an acid response sufficiently specific for ulcer cases to constitute a test of diagnostic value? (2) What part does hydrochloric acid play in the production of gastric pain?

The answer to the first question must clearly be in the negative, for pain typical in every way of ulcer, both as regards severity and localisation, was forthcoming, though not so commonly, in cases where a lesion of the gastric mucosa could undoubtedly be excluded (Table II.). General considerations would suggest that this must be so for the pains of ulcer can be simulated with absolute fidelity by a number of extra-gastric lesions, and must therefore almost certainly share with them a common mechanism. The discrepancy between the results described in this paper and those of Palmer can only be explained on the assumption that his cases were either examined during a period of quiescence or, more probably, were too few to bring out this point, for his series contains only one example each of chronic cholecystitis and subacute appendicitis, the lesions most likely to simulate ulcer in their symptomatology.

As regards the second question—the rôle of hydrochloric acid in the production of gastric pain—the matter is more difficult, and I am not prepared with a satisfactory answer. There seem to be three possible ways in which a chemical irritant might act: (1) by irritating the exposed nerve-endings in an area of ulceration; (2) by causing local spasm at the ulcer site and thus interfering with normal peristalsis; or (3) by causing a primary increase of tonus, as recently suggested by Poulton.[4]

The first two possibilities may be largely discounted, for in addition to being generally discredited on experimental grounds they fail to account for pain in the absence of structural defect. That there may be a local factor in certain instances is, however, suggested by some work of Ivy privately communicated to Alvarez,[5] which suggests that though not normally sensitive to painful stimuli, a mucous membrane, the seat of œdema or congestion, may become so.

The production of an increase in gastric tonus, and so pain, by hydrochloric acid lacks proof. All that can be said at the moment is that gastric pain typical in every way of ulcer has been produced by a number of experimenters, notably Poulton [4] and Hardt,[6] without calling in an acid factor; Hardt indeed in one case of gastric ulcer actually brought about relief by the introduction of 0·3 per cent. hydrochloric acid.

Palmer regarded hydrochloric acid as the adequate stimulus for ulcer pain normally present in the gastric juice; that it may be adequate in supernormal concentrations and at times in physiological ones he has abundantly proved, and his results have been confirmed in this paper, but when in his final summary [7] he states that acid is the normal stimulus for the pain mechanism I find it impossible to follow him, for my investigations so far as they go are definitely opposed to such a view. In the first place, the pain is rarely severe, and the patient, though able to identify it, will often volunteer the information that it is not nearly so severe as his typical distress, and this, be it noted, in the presence of acid values far in excess of those ever present in health or disease. The pain rarely shows itself when the acid concentration is at its maximum, that is, immediately after its introduction. Frequent analyses show that the acidity has usually undergone some reduction, at times considerable, before complaint is made. It is possible to explain this latent period on the grounds of a diminished threshold, but this is by no means always borne out by the patient's symptoms, and I have recounted one case of gastric ulcer of quite exceptional severity with a negative acid test.

With the weaker solutions, 0·25 per cent., I have frequently failed to get a satisfactory response when it was readily provoked by the stronger, and in the following experiment the reintroduction of gastric contents failed to reproduce pains of anything like the severity with which they were previously associated, and a subsequent injection of 0·5 per cent. HCl was practically without effect.

CASE R. B.—Big lesser curve ulcer; gastro-jejunostomy previously.

	Fasting juice, 15 c.cm.	Free HCl. 14 c.cm.*
9.45 :	200 c.cm. tap water.	
10.15 :	10 c.cm. only left	5 ,,
	200 c.cm. 0·5 per cent. HCl.	112 ,,
10.20 :	Pain severe.	
10.30 :	Stomach emptied 250 c.cm. Pain went at once.	64 ,,
10.50 :	Contents 250 c.cm. reintroduced.	
11.10 :	Pain very slight indeed.	
11.20 :	Pain gone.	
11.50 :	Stomach emptied 35 c.cm.	−12 ,,
11.50 :	100 c.cm. 0·5 per cent. HCl.	112 ,,
12.5 :	Pain slight.	
12.15 :	Stomach emptied 105 c.cm.	65 ,,
12.20 :	Pain much easier.	

* 1/10 N. soda per cent.

It might have been expected if hydrochloric acid were the normal stimulus for pain production that some relationship would be found between the type of pain the patient complained of, whether early or delayed after meals, and the latent period following the acid test, but no such relationship could be established, the proportion of positive results occurring during the first and second periods being roughly the same in the 47 cases in which this point was specifically noted. (Table IV.)

TABLE IV.

Type of pain.	No. of positives.	Period of test.		
		First.	Second.	Third.
Early	20	12	7	1
Delayed	27	17	9	1
	47	29	16	2

The use of histamine naturally suggests itself as a means of adding confirmation to the acid theory, but I have so far failed to produce any sensation whatsoever in ten ulcer patients, previously acid positive and still in an active phase, by the injection of one milligramme of histamine acid phosphate, though the subsequent acid values were well above normal; and in a recent experiment a failure with histamine was immediately followed by a positive result with 0·25 per cent. of HCl, though the acid values were at a considerably lower level.

CASE W. B.—Duodenal ulcer.

	Fasting juice 25 c.cm.	Free HCl. 10 c.cm.*
Zero :	1 mg. histamine acid phosphate	
10 mins. :	Stomach emptied 26 c.cm.	32 ,,

95 ,,	200 c.cm. 0·5 per cent. HCl. Pain at once.	
100 mins. :	Pain worse	137 ,,
110 ,,	Pain still severe. Specimen	51 ,,
	One drachm magnesium phosphate.	
115 mins. :	Pain easier	32 ,,
117 ,,	Pain gone	67 ,,

* 1/10 N. soda per cent.

It may be that the volume of the injected fluid plays a part, but I have no evidence to show that this is so, and I recall two cases in which the pain increased in severity after the stomach had been emptied.

Clinical observation from many aspects tends to support these findings and to suggest that the pains of peptic ulcer are independent of acid concentrations, for it is well recognised that severe and typical distress may be associated, though not commonly, with achlorhydria. The rapid relief of pain which follows the institution of an ulcer régime, whether associated with intensive alkalinisation as in Sippy's methods or following those of Lenhartz and Smithies in which alkalis play no essential part, is rarely accompanied by any lowering of acid values, and the present author [8] concluded that clinical improvement was independent of chemical change in a considerable number of cases, while in a few it was actually associated with a rise in acidity. Crohn and Reiss,[9] as a result of an intensive study of 34 ulcer cases treated by Sippy's methods, found a rough parallelism only between clinical and chemical improvement.

The view that alkalis relieve gastric pain by a process of neutralisation must also be subject to criticism, for it is noteworthy that such a result may be equally prompt in cases where the acid values are low, and indeed in some cases of carcinoma where free acidity is absent. Fractional studies, too, show that such neutralisation is of very brief duration, and is usually followed by a rise in acidity in excess of that previously recorded; yet the clinical relief outlasts the period of neutralisation and is unaffected by the subsequent hyperacidity. The explanation of the beneficial action of alkalis is probably that advanced by Spencer, Meyer, Rehfuss, and Hawke,[10] who found that these substances brought about a more rapid emptying of the stomach.

Such evidence, then, as I have been able to bring forward in this paper is opposed to any view which assigns to hydrochloric acid anything but a very minor rôle in the mechanism of gastric pain. The vagaries of gastric pain are well known. It comes and goes in a manner which suggests little dependence on chemical factors. The internal influences, infection, fatigue, tobacco, and the external ones, worry, rest, change, speak for a nervous rather than an acid control, and while it cannot be denied that the gastric acidity may occasionally be effective it must be emphasised that no theory of gastric pain can be regarded as satisfactory unless it will explain all the facts.

Conclusions.

1. Hydrochloric acid in concentrations of 0·5 per cent. will reproduce typical gastric pain in certain susceptible individuals suffering from painful disturbances of gastric function.
2. The pain occurs independently of any local disease in the stomach or duodenum.
3. The rôle of hydrochloric acid is discussed and the view put forward that it plays no essential part in ordinary pain production.

I gratefully acknowledge the valuable help I have received from Miss Fisher and Miss Graham, nursing sisters, in carrying out the tests, and from Mr. Garfield Thomas, biochemist to the hospital, who undertook numerous chemical analyses.

A CONTROL OBSERVATION WITH SANOCRYSIN.

BY B. R. CLARKE, M.D. BELF.,
MEDICAL SUPERINTENDENT, FORSTER GREEN HOSPITAL, BELFAST;
AND
H. G. K. HADDICK, M.B., B.CH. BELF.,
FORMERLY HOUSE PHYSICIAN AT THE HOSPITAL.

SINCE May, 1925, certain patients suffering from pulmonary tuberculosis have been treated with sanocrysin at the Forster Green Hospital. Marked improvement followed the treatment in some instances, and encouraging reports from other observers have been published. It was, however, decided to carry out a control observation during 1927. The difficulty of assessing the value of any treatment of pulmonary tuberculosis is notorious, and it is the opinion of the writers that no treatment has gained anything like general acceptance, except the régime known as sanatorium treatment and in selected cases collapse therapy. Thus, after many years' trial, some competent physicians have abandoned tuberculin therapy, while others continue to advocate it. Alpine treatment, once regarded as the *ne plus ultra* of the therapy of tuberculosis, also has its critics. Sanocrysin treatment is certainly not free from danger, and it is expensive and troublesome—three special reasons why it is imperative to assess its value, if it is to be considered at all. Several observers, some of whom are undoubted authorities on the treatment of tuberculosis, have recorded no good results from sanocrysin treatment.

These were some of the considerations which suggested an observation of the results of sanocrysin treatment with a control group of similar cases. Moreover, it was not practicable to treat more than a limited number of patients, and therefore it seemed justifiable to select the cases in such a way that a control observation could be made. Sanocrysin treatment would not have been withheld from any patient in the control group—if he had asked specially for it and had been considered a suitable case.

Dr. F. R. Walters[1] emphasises certain conditions which must be fulfilled before a treatment of pulmonary tuberculosis can be tested. So far as possible these conditions have been fulfilled in carrying out the observation. The conditions were as follows:—

(1) All patients admitted during 1927 who had tubercle bacilli in the sputum were divided into two groups alphabetically. Those whose names began with the letters A to K did not receive sanocrysin treatment; those whose names began with the letters L to Z received sanocrysin treatment, if they appeared suitable and were willing to have it. (2) Patients readmitted to the hospital or who remained for less than six weeks were excluded from the observation. Of course this method does not ensure that the two groups would be strictly comparable, but it excludes any conscious or unconscious selection of the more favourable cases for the special treatment. It appeared, from a common sense point of view, that if the control group did as well as the sanocrysin-treated group, it might reasonably be inferred that sanocrysin was without much value. On the other hand, if the results in the sanocrysin-treated group were much better, there would be, at least, a case worth further examination. At the same time, an attempt was made to compare the two groups in every respect which might have a bearing on prognosis.

The following factors were considered: (1) Sex; (2) family history; (3) duration of disease from first symptoms; (4) temperature on admission to hospital; (5) pulse-rate on admission to hospital; (6) presence of cavity clinically; (7) presence of cavity radiologically; (8) extent of involvement of the lungs radiologically; (9) classification, devised by the Society of Superintendents of Tuberculosis Institutes; (10) complications.

Altogether[2] 112 patients having tubercle bacilli in the sputum were admitted to hospital during 1927; 2 of these were readmissions and 13 remained less than six weeks in hospital (one readmission in A to K group, one readmission in L to Z group; five remained less than six weeks in A to K group; eight remained less than six weeks in L to Z group). The 97 patients to be considered were divided as follows:—40 patients whose names began with the letters A to K; 57, L to Z.

The following tables compare the condition of the two groups on admission to hospital. Throughout this paper normal temperature is regarded as 98·6° F.;* subfebrile temperature is regarded as 98·6° to 99·6° F.;* febrile temperature is regarded as higher than 99·6° F.*

Normal pulse-rate is regarded as: Not more than 80 (*a*) and 84 (*b*).

Moderate pulse-rate: 80–96 (*a*) and 84–100 (*b*).

Rapid pulse-rate: More than 96 (*a*) and more than 100 (*b*).

(*a*) Evening pulse-rate for men, and (*b*) for women.

Comparison of Sanocrysin Group L to Z with Control Group A to K.

Tuberculous laryngitis	4	8	12
Fistula-in-ano	1	3	4
Cervical adenitis	1	2	3
Tuberculous osteitis of femur ..	—	1	1
Spontaneous pneumothorax ..	—	1	1
Tuberculous meningitis	1	—	1
Thrombosis of femoral vein ..	1	—	1
Tonsillitis	—	4	4
Hæmorrhoids	—	1	1
Goitre	—	2	2
Duodenal ulcer	—	1	1
Epilepsy	—	1	1
Nephritis	2	—	2
Total	10	24	34

The comparison of the two groups shows that the sanocrysin-treated group appears to have a more unfavourable prognosis than the control group with reference to the temperature on admission, pulse-rate on admission, presence of cavity, clinically and radiologically, and extent of lung involvement radiologically. On the other hand, the control group contained a higher proportion of patients whose first symptoms appeared more than six months before admission.

Sanocrysin treatment was attempted or completed in 39 patients of the L to Z group. Artificial pneumothorax was tried in 12 patients of the L to Z group and 14 patients of the A to K group.†

---

* Evening mouth temperature.

† The high proportion of artificial pneumothorax cases is largely due to the fact that patients are often selected for admission by the tuberculosis officers because of their suitability for this treatment.

In considering the results of treatment two patients in the A to K group and two patients in the L to Z group, who are still in hospital, have been regarded as discharged on Oct. 17th, 1928, their condition on that date being regarded as their condition on discharge.

Results.

1. *Immediate Result of Treatment, as shown by Condition on Discharge.*

Group.	Quiescent.	Improved.	Unchanged.	Worse.	Total.
A to K (control group)	4	28	5	3	40
L to Z (sanocrysin group)	20	26	7	4	57

Of the patients in the control group A to K five had an artificial pneumothorax with satisfactory collapse (quiescent, 2; improved, 3). In the sanocrysin-treated group L to Z four patients had artificial pneumothorax treatment with satisfactory collapse (quiescent, 2; improved, 2). Excluding these nine cases the results are shown below.

2. *Immediate Result (excluding Nine Cases which had a Satisfactory Artificial Pneumothorax).*

Group.	Quiescent.	Improved.	Unchanged.	Worse.	Total.
A to K (control group)	2	25	5	3	35
L to Z (sanocrysin group)	18	21	7	4	53

3. *Sputum on Discharge from Hospital.*

Group.	No tubercle bacilli or no sputum.	Bacilli present, but less than 1/10 number of bacilli on admission.	No improvement.
A to K ..	6	7	27
L to Z ..	24	8	25

4. *Result of Treatment with Reference to the Duration of Stay in Hospital.*

Time in hospital in months.	Group.	Quiescent.	Improved.	Unchanged.	Worse.

5. *Number of Patients known to be Dead on Dec. 31st, 1928.*‡

Group.	Number.	Dead.
A–K	40	11
L–Z	57	7

Note on the L to Z Group from which the Sanocrysin Cases were Selected.

There were 57 patients in this group and 39 of these had sanocrysin treatment. In eight cases the treatment was considered unnecessary; in seven it was contra-indicated, and three refused it.

Of the 39 patients treated with sanocrysin the treatment was completed in 30 and given up in 9. The reasons for abandoning treatment in these 9 cases were as follows:—

Failure to improve ..	3	Progressive loss of weight ..	1
Diarrhœa	2	Focal and general reaction	1
Albuminuria	1	Acute tonsillitis	1

The results of treatment in these 9 cases were as follows:—

Quiescent	0	Unchanged	4
Improved	2	Worse	3

Considering the 30 cases whose treatment was completed, the results were as follows:—

Quiescent	15	Unchanged	1
Improved	13	Worse	1

Of the 30 patients whose treatment was completed 26 gained and 4 lost weight during the course of the injections. Of the 9 patients whose treatment was not completed 2 gained and 6 lost weight. One patient was not weighed.

It is not the purpose of this article to discuss the details and technique of sanocrysin treatment. The method used in all cases was the system of graduated dosage which is now widely employed. Graduated dosage has been the invariable rule at the Forster Green Hospital since August, 1925, and the loss of weight, which was so common a feature of the first cases, is now exceptional. Thus of the 39 cases treated in 1927 28 gained and 10 lost weight during the injections. The average gain of weight during the treatment was 7 lb., the greatest gain being 31 lb. in 14 weeks. The average loss of weight was 2½ lb., the greatest loss being 5¼ lb.

The complications which occurred during the sanocrysin injections were as follows:—

Febrile reactions following an injection	13	*Diarrhœa*	2
Subfebrile reactions following an injection ..	12	Stomatitis	1
Well-marked albuminuria	9	Dermatitis	1
Transient albuminuria ..	8	Neuritis	1
Vomiting	3	Focal and general reaction	1
		Œdema of the eyelids ..	1

Two other clinical observations of cases, treated with sanocrysin and compared with similar "control" groups, have been published by Würtzen[3] and Bie and Andersen.[4] Both these observations point to the conclusion that the sanocrysin-treated cases do better than untreated cases, and the results obtained at the Forster Green Hospital appear to justify a similar conclusion.

---

‡ All patients included in the observation will be traced in January, 1929.

LEEDS GENERAL INFIRMARY.—About 14,500 in-patients were admitted last year, 1000 more than in 1927, and surgical cases alone amounted to 5000. Notwithstanding that the average stay of each in-patient is only 11 days, the waiting-list contains more than 1000 names. The out-patients exceeded 50,000, an increase of about 3000. Patients suffering from motoring accidents grew to 1135. Their treatment cost £1775, of which only £167 was repaid. The deficit on ordinary expenditure was £23,500 and the accumulated deficit of the last eight years is £76,550. The income from annual subscribers last year was only £7100.

DONATIONS AND BEQUESTS.—Mr. John Allison Barr, of Pollokshields, Glasgow, left among other bequests, £2000 to Glasgow Royal Infirmary; £1000 each to the Western Infirmary, Glasgow, the Victoria Infirmary, the St. Andrews Ambulance Association, the Glasgow Ear, Nose, and Throat Hospital, the Royal Hospital for Sick Children, the Glasgow Eye Infirmary, and the Royal Glasgow Asylum for the Blind; and £200 to the Royal Samaritan Hospital for Women, Glasgow.—Mr. James Haggart Dewar, of Whittinghame Drive, Kelvinside, Glasgow, left £2000 to the Royal Hospital for Sick Children, Glasgow, and £1000 to the Princess Louise Hospital for Limbless Sailors and Soldiers, Erskine.

Clinical and Laboratory Notes.

AN OBSCURE CASE OF ULCERATIVE ENDOCARDITIS OF THE TRICUSPID VALVE.

BY J. F. WILKINSON, M.B., M.SC., PH.D. MANCH.,
HOUSE PHYSICIAN, MANCHESTER ROYAL INFIRMARY.

THE difficulty in establishing a diagnosis of malignant endocarditis of the tricuspid valve, recorded by Scott Pinchin and H. V. Morlock in THE LANCET of Feb. 2nd (p. 230) is of considerable interest in view of a similar case recently at the Manchester Royal Infirmary under the care of Dr. F. Craven Moore, who allows me to place the following particulars on record.

A policeman, aged 47, was admitted to the Manchester Royal Infirmary on Dec. 24th, 1928, complaining of extreme dyspnœa and excessive perspiration, together with a cough and abundant expectoration. He had had bronchitis for the last 28 years, with more severe exacerbations during the winter months. Five years before he had had an attack of dyspnœa and profuse perspiration, not so acute as the last attack, which had improved after rest in bed. Two years before (1926) he had been confined to bed for two weeks with "rheumatic" pains in both feet, more particularly in the toes, no other joints being affected. Although he had noticed occasional slight œdema of the ankles during 1927, he was well from that time until the last week in November, 1928—the commencement of the present attack. He complained of a slight pain over the right hypochondrium and xiphisternum, which he thought was due to flatulence, and this was followed by two "shivering attacks" in one day. He was better next day and did not come under medical supervision at this stage. Finding himself getting very short of breath and perspiring more profusely than usual, he stayed in bed from Dec. 15th until Dec. 17th, when he returned to duty, but was not able to [illegible]. From that date, until his admission into the Manchester Royal Infirmary a week later, he was confined to bed with an increasing degree of dyspnœa, perspiration, cough, and expectoration. No typical asthmatic attack was described, nor was there any history of rash, purpuric spots, hæmatemesis, hæmoptysis, or hæmaturia. Urine and bowels had been normal, and the patient had abstained from tobacco and alcohol for the last five years and one year respectively.

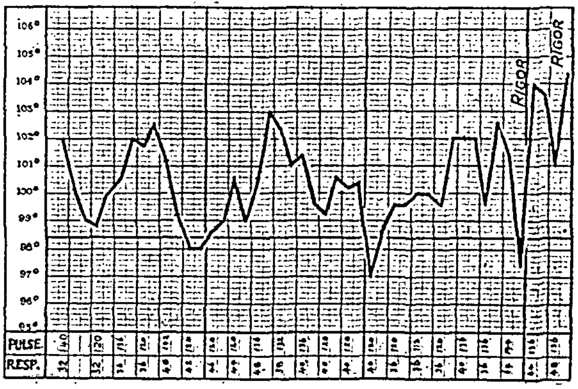
Previous Medical History.—He had been a policeman since his discharge from the army after the Boer war. While in South Africa he had contracted typhoid fever, malaria, and double pneumonia (twice), but had had no other illnesses.

Condition on Examination.—He was a very heavily built man, weighing 20 st. He was very cyanosed and extremely dyspnœic and there was a profuse perspiration, especially over the upper half of the body. His teeth showed evidence of pyorrhœa, but the tonsils were not enlarged and there were no enlarged glands. There were no signs of œdema of the legs, ascites, purpuric or tender spots, rash, or retinal hæmorrhage. His respiration-rate was 32, his temperature 102° F., and his pulse was 140 and regular. The apex-beat was not determined and cardiac dullness was obscured by the emphysema and the thickness of the chest wall. Clear auscultation was difficult owing to the respiratory adventitious sounds and the extreme dyspnœa, which prevented the patient from holding his breath, but there appeared to be a somewhat indefinite, soft systolic murmur between the xiphisternum and the apex. There was no venous pulsation in the neck, and the liver and spleen were not palpable. The lungs were emphysematous. There were generalised rhonchi, moist sounds at both bases, and a slight friction rub at the left base posteriorly. Nothing abnormal was detected in the very large abdomen. Urine and fæces were normal.

Course of Illness.—The patient was sent to the Manchester Royal Infirmary as a case of acute bronchitis with asthma, and the progress was as follows. There was extreme dyspnœa and, although restless, he was only able to turn in bed with assistance. A typical asthmatic attack occurred the first night after admission. Perspiration was very free throughout the course of the illness and did not respond to treatment. The temperature was very irregular (see chart), but the first rigors (three in number) only occurred on Jan. 13th, 1929, three weeks after admission, and were repeated two days later. He complained of slight pain in the left side of the chest posteriorly; there was no abdominal pain. There was much frothy mucous sputum (no tubercle bacilli were found), but no hæmoptysis or staining until Jan. 14th. Cough was variable but not excessive. Two separate and independent attacks of melæna occurred in the second and third weeks respectively after admission. Daily examination of the cardiac condition did not disclose any demonstrable alterations. The urine never contained albumin. During the last week of the illness the left arm and hand became swollen and very tender, as later did the right. This was due to fixation abscesses, from which a practically pure culture of pneumococci was isolated.

On Jan. 14th the *blood count* was as follows: red cells, 3,288,000; white cells, 11,600; hæmoglobin, 60 per cent.; *colour-index*, 0·94; *polymorphonuclears*, 72·75 per cent.; lymphocytes, 22·75 per cent.; large mononuclears, 4·25 per cent.; eosinophils, 0; basophils, 0·25 per cent. Slight anisocytosis and poikilocytosis was present. No abnormal cells were seen. Platelets were abundant.

On Jan. 15th, 1929, there was evidence of consolidation at the base of the left lung behind the mid-axillary line, the illness terminating next day. The patient was unimpaired mentally, and the physical condition did not alter appreciably from the date of admission until the last 36 hours. No radiographic examination could be made owing to the condition and size of the patient.



Post-mortem Findings.—The pericardium was normal. The heart weighed 440 g. The myocardium was of good colour and slightly soft. The right auricle only was moderately dilated, and there were no thrombi. The right ventricle showed slight dilatation but no hypertrophy; the left showed slight dilatation and hypertrophy. The tricuspid valve admitted three fingers; the valve substance showed no old lesion but there was a mass of crumbling vegetations, the size of a hazel-nut, based broadly on the middle of the anterior cusp, and a small mass, the size of a pea, on the septal cusp. The vegetation presented to the ventricular side, which also showed ulceration. The mitral valve admitted two fingers and showed no stenosis; the chordæ tendinæ to the anterior cusp were definitely thickened but not contracted. The anterior cusp showed slight roughening and minute vegetations at its middle portion. The aortic and pulmonary valves were normal. There was moderate atheroma of the aorta and coronary arteries.

Both pleuræ were normal. The right lung weighed 640 g. and showed a moderate degree of vesicular emphysema, well aerated throughout, but no œdema nor consolidation. The left lung weighed 760 g. and showed vesicular emphysema; the lower lobe was somewhat congested and the seat of slight consolidation, chiefly posteriorly; the upper lobe was well aerated throughout. There was moderate congestion of the larger bronchi. There was a group of seven ulcers round the lesser curvature of the stomach near the cardia; the largest, on the posterior wall of the fundus, was 3 by 2 cm., the smallest 1 by 0·5 cm.; they penetrated the mucosa but based on the submucosa, and were evidently of recent origin. The spleen weighed 460 g. and was of moderate consistence, dull red and septic. The liver weighed 2360 g.; a fairly well-marked fatty infiltration accentuated the lobules. The biliary passages were normal. The thyroid gland weighed 90 g. and was fairly large and full of colloid. The kidneys weighed 260 g. each; the capsules stripped normally and the surfaces were smooth, but the cortices were paler than normal; there were no infarcts or abscesses. On the outer aspects of both upper arms there were fixation abscesses at the sites of therapeutic injection.

Several points of interest arise in the consideration of this case. The excessive perspiration and extreme dyspnœa were notable features and, coupled with the temperature, pulse, and respiration rates and the friction rub at the left base, suggested the possibility of an early pneumonia. The progress of the case did not fully justify this diagnosis and, in view of the history of recent onset of asthma in a man of 47 years of age, the possibility of a thoracic neoplasm was also considered but did not correspond with the clinical condition. The absence of definite cardiac signs, embolic phenomena, or positive blood-culture (cf. Scott Pinchin and Morlock, loc. cit.) or rigors was very striking, the irregular pyrexia being the only sign indicative of a possible cardiac lesion. The sudden melæna occurring in the second and third weeks raised the question of typhoid fever, but appropriate investigation did not support this. The thrombotic gastric ulcers were the only definite secondary results discovered that might be ascribed to the cardiac lesion, and it is interesting to note that no gastric symptoms were described.

Acknowledgment is made to Prof. J. Shaw Dunn for permission to use the records of his post-mortem investigation of this case.

A NOTE ON
LEPROUS LESIONS OF THE SCALP.

By A. R. DAVISON, M.R.C.S. ENG.,
MEDICAL OFFICER, EMJANAYANA LEPER INSTITUTION, SOUTH AFRICA.

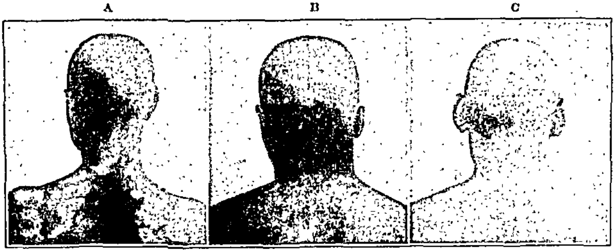
IN 1927 two native patients of the Emjanyana Leper Institution were discovered to have leprous lesions of the scalp. This is considered to be a very unusual situation. Thus Rogers and Muir ("Leprosy," 1925, p. 143) state:—

"Leprosy bacilli have been found in the corium of the skin over almost the whole body. A noticeable exception to this is the scalp, where, as far as we are aware, leprous lesions are seldom or never found."

They also say (p. 168):

"It is remarkable that there were no lesions of the scalp recorded. We have never yet come across any leprous lesions of the scalp, either as a primary or as a subsequent lesion, though we have met with anæsthesia of the scalp due to leprous disease of the supra-orbital nerve."

FIG. 1.



CASE 1.—Maculæ extending to scalp. CASE 2.—Maculæ behind ears and over occiput. CASE 3.—Nodular leprosy of scalp.

Frequency of Scalp Lesions.

Over a period of nine months all new admissions to this institution have been shaved as a routine, and an examination of their scalps has revealed the following figures:—

Total No. of cases.	Nodular infiltration of scalp.	Maculæ in scalp.	No leprous lesions in scalp.
Males, 72.. ..	7	24	41
Females, 53 ..	2	18	33

The percentage of scalp lesions in males is 43 and in females 38. The lesions of the scalp are similar to leprous lesions in other parts of the body, in that they show *depigmentation, anæsthesia, and erythematous* and raised margins. Lepra bacilli are present in clip smears from these areas. Maculæ are difficult to discern in an unshaved scalp, but nodular infiltration causes a falling of the hair over the affected area and so may be more easily noticed. Examples of our findings are:—

CASE 1, female, is in the reactionary phase of the maculo-anæsthetic type, with multiple coalescing maculæ of the scalp. The maculæ have raised erythematous, scaling margins. The centres are anæsthetic. There is an infiltrated plaque over the occipital protuberance. Clip smear three inches above right ear showed lepra bacilli. (Fig. 1A.)

CASE 2, male, has maculo-anæsthetic type. Six well-defined maculæ involve the lower border of the scalp. Two *are situated below the occiput, one is behind the right ear* and three behind the left ear. The maculæ are anæsthetic and have raised margins. Lepra bacilli are present over the occiput. (Fig. 1B.)

CASE 3, male, has nodular type infection. There is partial baldness, which extends in parallel lines from the brow to the back of the neck. The skin of the bald areas shows interfollicular infiltration, except over the occiput, where the skin has become papery. Clip smears taken two inches above the occiput and four inches above the right ear show lepra bacilli. (Fig. 1C.)

It is strange that our South African natives should be liable to leprous lesions of the scalp, whereas the natives of India are exempt—though the lesions we found were not suspected and were almost invisible until the scalp was shaved.

Predisposing Factors.

Factors which may predispose our natives to these lesions are:

1. The negroid type of hair, which is short, frizzled, and scanty compared to that of a European or an Indian. The blood-supply, therefore, is probably less in proportion. The scalp, being less protected by the hair, is more liable to come into direct contact with leprosy-infected articles.

2. *The state of personal cleanliness and hygiene is* very poor amongst the natives. Pediculosis is common, and it is not unusual to see natives searching one another's scalps with as much gusto as monkeys. Scratching and consequent abrasion of the scalp is therefore not uncommon.

3. Amongst other causes of scalp injuries we may mention the native stick fights, the habit of carrying articles on the head, and the fact that a stone or a block of wood is the usual head-rest at night.

It is obvious, therefore, that the scalp of the South African native is constantly exposed to the entrance of germs, and that the low state of hygiene predisposes to the development of bacilli which have once gained entrance.

The method which we have used for demonstrating the lepra bacilli is simple and efficacious. A fine *needle is passed through the skin at the edge of the* macula and the transfixed skin is clipped through below the needle. The needle serves the double purpose of rendering the part bloodless and enabling the clipping to be easily transferred to the slide, over which it is firmly smeared. The slide is stained in the usual way.

Medical Societies.

ROYAL SOCIETY OF MEDICINE.

GASTRIC CHEMISTRY.

AT a meeting of the Section of Medicine, held on March 26th, Dr. ARTHUR F. HURST, the President, being in the chair, a discussion on gastric chemistry was opened by Prof. LEONARD PARSONS (Birmingham), who read a paper on the significance of

Achlorhydria in Infancy and Childhood.

The subject was, he said, of peculiar importance because of the two opposing views which had been advanced. Faber held that the achylia gastrica of adults was the result of a deep-seated hæmatogenous gastritis, which itself was the result of acute infective disorders in childhood and infancy. Brocq found that achlorhydria occurred in the infectious disorders of childhood, and that it might persist for years after the original disease had been recovered from. Brocq had also investigated the stomach of children who had suffered from infectious disorders and found achlorhydria, with evidence of chronic gastritis. That authority never found achylia in healthy children. Pyelitis might show itself first by diarrhœa and vomiting, and that was associated with achylia. It had been suggested that this diarrhœa was due to extension of organisms from the colon and the small intestine. The suggestion had been advanced that there existed a constitutional achylia gastrica; and Dr. Hurst had stated that there was a constitutional, often a familial, achylia gastrica which was not associated with any known structural change in the mucous membrane of the stomach. The speaker had found cases of achylia which seemed to permit of no other explanation. At the Birmingham Children's Hospital, however, an attempt had been made to attack the problem anew by means of test-meals. The result was that he believed he was now able to show that Dr. Hurst's ideas were not correct. Dr. Parsons submitted five propositions: (1) Achlorhydria might be due to a rapid emptying of the stomach, though sometimes the emptying was found to be slow. (2) It might be due to the type of test-meal used. Or (3) to the presence of enteral infections. (4) In all cases showing supposed achlorhydria there was evidence of secretion of hydrochloric acid, so that it was a false achylia. (5) There was no evidence of innate hyperchlorhydria.

He had investigated 51 cases, and ten of them showed no free hydrochloric acid in the test-meal. The latter was the meal which the child had been having; he had not been using a standard meal. Foods differed in their buffer value. If there was no free hydrochloric acid present, the buffer capacity was the total acid plus the free acid present. Cow's milk had a higher buffer capacity than had human breast milk. If a child was ill, its difficulty in producing that quantity of free hydrochloric acid might lead to achlorhydria. He had been using acid milks—i.e., containing lactic acid and hydrochloric acid. The total acidity curve was made up of protein, HCl, organic acids, and acid salts. Mineral chlorides were found to make no difference to the acid curve. The amount of lactic acid produced in the infant's stomach was insignificant, and therefore the rise of the acidity-deficit curve must be due to the secretion of hydrochloric acid, and that occurred in all cases of achlorhydria.

In artificially fed children the hydrochloric acid was nearly always low. He had arrived at the conclusion that there was no such condition as innate achylia gastrica. He was not clear whether the latter in adults was to be considered the same as the achlorhydria of childhood. Some cases of pernicious anæmia showed no rise in the acid-deficit curve; but in the adult it might be a further stage of the false achylia in childhood.

Dr. W. S. C. COPEMAN (London) read a paper, by himself and Dr. N. GRAY HILL, on

Fractional Test-meals in Childhood.

The submission was made by a series of charts shown on the screen, and was based on the investigation of seven cases in which there was no free hydrochloric acid in 66 children examined, and who were without gastric disorders or history of such. The seven children were of normal height and weight for their age, and their ages ranged from 12 to 15 years. All the children were on a normal mixed diet, and appeared to have no craving for any particular kind of food. The general result was that the total acidity was parallel with the free hydrochloric acid.

Dr. S. W. PATTERSON (Ruthin) followed with a paper on the

Pathology of Gastric Secretion,

setting out the results of an analysis of 662 cases in which a Rehfuss test-meal was given, and estimations were made of total chlorides, total acidity, and free hydrochloric acid in samples taken at 15-minute intervals. He divided the cases into groups: (1) those showing various types of gastric lesion; (2) those showing various extragastric lesions which might presumably cause reflex disturbance, such as inflammation of the appendix or gall-bladder, gall-stones, colitis, abscesses of teeth, &c.; (3) normal. Considerable variation occurred in the normal group, as Bennett and Ryle had already noted. Achlorhydria was present in some. There was a tendency for duodenal ulcer cases to give a superacidity curve, this sometimes rising by steps until the time the stomach was emptied. In gastric ulcer the curves were normal except when the ulcer was in the pyloric region. Cases of gastritis and carcinoma of the body of the stomach showed subacidity. As to conditions affecting the rest of the alimentary tract, appendicitis cases gave curves within normal limits, but there was a tendency to superacidity in cases of cholecystitis, also in some patients with colitis and diverticulosis of the colon. The acidity curve was lowered by such infections as tubercle, and by septic conditions (tooth abscesses, &c.). When the total acidity was correlated with the state of the pylorus and duodenal cap as revealed by the X ray screen, a grouping took place into those of pyloric or duodenal ulcer with superacidity, pyloric rigidity (as in carcinoma with achlorhydria, pyloric compression, or irritability or spasm) which tended to show some superacidity, and normal.

The Rehfuss test-meal, he said, gave little stimulus to appetite, therefore the results were largely of the chemical or second phase of gastric secretion. An interpretation of the results as variations in response of the secreting fundus glands and the hormone-producing glands of the pylorus offered an explanation of the pathology of gastric secretion. Gastric secretion was altered in cases in which the secreting part of the stomach was replaced, as in carcinoma of the body of the stomach; or when it was absent or atrophic, as in pernicious anæmia; or when it was rendered abnormal by inflammation, as in gastritis; or when it was reduced in efficiency by the presence of tubercle or sepsis in some other part of the body. Dr. Patterson believed that in other cases the receptivity of the mucous membrane of the pylorus to chemical stimulation and in its motor functions lay the key to the pathology of gastric secretion.

Dr. J. F. VENABLES (New Lodge Clinic) read a communication by Dr. T. W. TURNER and himself on the true

Frequency of Hyperchlorhydria in Duodenal Ulcer.

He was, he said, using the classification which Bell arrived at in 1923 as a result of the analysis of 425 test-meals, giving six varieties. It was generally accepted that in duodenal ulcer the hyperchlorhydria provided the largest percentage of test-meals met with. Cases had often been met with in which the diagnosis was established by X ray findings, a history of occult blood in the stools, &c., and in which the test-meal had belonged to the normal, or even the hyperchlorhydria group. There was no constant test-meal in gastric ulcer. He spoke of an investigation of 40 cases, of which 27 were duodenal ulcer and 13 gastric ulcer. They were given test-meals during the initial investigation, and each case was treated medically, with rest, diet, alkalis, removal of any focal sepsis, &c. A second test-meal was given after general evidence was obtained that the ulcer had satisfactorily responded to medical treatment. Of the 27 duodenal cases, 22 showed a different test-meal after medical treatment had apparently been satisfactorily carried out, and in each case the difference was one in the direction of increased acidity. Five cases showed no variation, four of them originally showing a test-meal which brought them into hyperchlorhydria. One case was that of a man with duodenal ulcer, who had had several hæmorrhages, and deformity evident to X rays. He had hyperchlorhydria, and in every specimen there was a great excess of mucus. He had septic teeth and tonsils. He was treated on medical lines, and the septic foci dealt with. After the ulcer had responded well, the mucus disappeared and he had excessive hyperchlorhydria. Hyperchlorhydria seemed to be an essential part of the duodenal diathesis, not the response to the presence of active ulcer. The rise in acidity he attributed to the disappearance of the gastritis which was present, associated with active duodenal ulcer. In the 13 cases of gastric ulcer there was an increased acidity after the satisfactory conclusion of treatment in 10; the other three showed no rise, though there was no fall either. The final test-meal in that group showed ten cases with a test-meal belonging to the highest group—i.e., hyperchlorhydria—two were "high normals," and one was a hypochlorhydria, the latter having shown achlorhydria when the investigation was started. He suggested that the large number of achlorhydrias after treatment was due to the same factor as in duodenal ulcer, after the crater associated with it had disappeared. He hoped to continue the investigation and have a larger series to present.

Dr. T. L. **HARDY** (Birmingham) then read an abstract of a paper which appears in full on p. 711 of this issue.

Dr. W. **MORRELL ROBERTS** (Manchester) submitted a preliminary paper on the

Effect of Oils on Gastric Secretion.

The inhibitory effect of oils and fats on gastric secretion had, he said, been noted many times, but he was not aware of any explanation having been advanced. The diminished acidity of the gastric content in the presence of oil was not due simply to the fact that oil failed to stimulate secretion. It was said that oil inhibited secretion by forming a layer over the gastric mucous membrane, and so protecting it from stimulation by the food constituents, but this would not account for the inhibition of psychical secretion. The purer the specimen of oil used, the more pronounced was the effect, but there was still an unexplained factor which he had not discovered. Additions of oleic acid to pure oils did not greatly interfere with their efficiency. What did seem definitely to emerge was that the higher the iodine value of the oil used, the more effective was it in reducing the stomach secretion. The iodine values in the various oils used in the inquiry were as follows: linseed, 185; cod-liver oil, 153; pea-nut oil, 105; almond, 93; olive, 84. Though oil inhibited gastric secretion in varying degrees when stimulation was supplied by food in the stomach, it was unable to do so when the gastric cells were stimulated by histamine in the circulating blood. If it were true that psychical secretion were inhibited by oil, it must be in virtue of the action of the oil within the stomach.

Discussion.

The **PRESIDENT** (New Lodge Clinic) said he felt that Prof. Parsons was wrong in the view he expressed in his paper, and the reason was evident in contrasting his results with those set out in the paper of Dr. Copeman and Dr. Gray Hill. The children spoken of by Dr. Parsons were marasmic, whereas the other children dealt with were healthy. There was no particular reason why children with true constitutional achylia should be marasmic. He accepted the statement of Dr. Parsons that all the cases he described were instances of false achylia—i.e., they had not achylia. It was most important to distinguish between achylia and achlorhydria. Achylia gastrica was the complete absence of gastric secretion; achlorhydria was simply absence of free hydrochloric acid. Only very few cases of the latter were due to the former. In achlorhydria mucus was always present; and on washing the stomach out and then giving another test-meal there was, almost invariably, a return of free acid. The wrong treatment was to give these patients acid, because the physician could remove the gastritis and allow them to secrete their own acid by means of systematic lavage. Achylia gastrica he regarded as an inborn error of secretion, unaccompanied by any anatomical change in the gastric mucous membrane. This was strongly supported by the frequency with which the condition was familial. True achylia was chiefly found as an associate of Addison's anæmia. Occasionally one came across a true achylia gastrica in a person apparently healthy, and on going into the family history one learned that relatives had died of pernicious anæmia.

He did not agree with Dr. Patterson that there was atrophy of mucous membrane in pernicious anæmia, as the speaker had found that the cells were present, they simply were unable to secrete. Constitutional achylia was compatible with good health, though the subjects of it were predisposed to diseases more than were ordinary people. He did not think the position of the ulcer in the stomach had anything to do with the secretion. He believed that hyperchlorhydria was the cause of the ulcer, not the result. The recent work of Dr. Venables showed there was, in many cases before the gastric ulcer developed, an excessive acidity associated with a different type of stomach, a type which made the stomach a likely place for ulcer. Dr. Hurst contended that the person with the average stomach could not get an ulcer. And the development of a growth in the stomach did not produce the acidity, and no one had ever seen the acid gradually reduced and disappear as a result of carcinoma of the stomach.

Dr. E. P. **POULTON** (London) said he did not think it possible that a person could have normal cells in the stomach without producing hydrochloric acid; and if a cell ceased to function it must atrophy. Faber said he had never yet seen a case in which there had been complete absence of hydrochloric acid and absence of ferment too. The speaker suggested that all the cases of achylia were cases of achlorhydria, and probably owning gastritis as a cause. He considered that acid was very important in the initiation of an ulcer, but that it had no part in its continuance. Experimentally, the attempts to keep ulcer alive by means of hydrochloric acid had been disappointing. The chronicity was due, he thought, to mechanical changes. Success in the treatment of gastric and duodenal ulcer had been attributed to giving alkalis, but what was really given were alkaline carbonates and their stimulating action, liberating CO_2, and accelerating the emptying of the stomach.

Dr. G. W. **GOODHART** (London) appealed to investigators that when they were reporting experiments involving test-meals they should give readers an indication of the times of the emptying of the stomach; also as to whether there was a mixture of gastric contents or of gastric juice alone in an empty stomach. It detracted seriously from the drawing of accurate conclusions when these essential particulars were not stated. He considered that achlorhydria from carcinoma was much more common than achlorhydria from gastritis. If the President's view was correct that the carcinoma was always preceded by gastritis, Dr. Goodhart thought there should be far more cases of achlorhydria due to plain gastritis than were seen, unless a large proportion of gastritis cases passed on to carcinoma.

The readers of papers briefly replied.

SECTIONS OF COMPARATIVE MEDICINE AND NEUROLOGY.

ON March 27th a combined meeting of these Sections was held, with Major-General Sir JOHN MOORE, President of the Section of Comparative Medicine, in the chair, to discuss

Encephalomyelitis in Man and Animals.

The CHAIRMAN referred to the poisoning of animals by sewage, which, he said, led to nervous symptoms. During the late war he had been requested by General Headquarters to go and see a farmer whose property was on the lines of communication, and who had lost some animals, whilst others were ill, from alleged carbide poisoning of the ponds. It turned out that the cause was impregnation of the water by sewage.

Mr. I. A. GALLOWAY opened the discussion on behalf of the Section of Comparative Medicine, and dealt with diseases affecting domestic animals, in which the chief pathological changes were found in the nervous system. He spoke first of the enzoötic encephalomyelitis of horses, commonly known as Borna disease, from the locality in Saxony, where a severe visitation occurred between 1894 and 1896. This disorder was found on the continent and in America, but no cases, said Mr. Galloway, had so far been reported as occurring in this country.* It seemed to be the same disease as that met with in sheep and cattle. It was infectious, and experiments had shown that animals could be infected by introducing the virus into the nose or by ingestion. The extent of the spread of the disease seemed to be influenced by climate, for it was certainly more prevalent under moist atmospheric conditions and certain districts seemed to be especially affected. The mortality was always high, varying from 70 to 80 per cent., and the cause of the disease was a virus of ultra-microscopic minuteness. In spontaneous cases the incubation period had not been determined; in experimental cases a long time elapsed between inoculation and death. In the rabbit this period was about 30 days, in the monkey 89 days, in the rat or mouse 20 to 82 days, and in the horse 50 to 80 days. The lesions in the peripheral nervous system were important, as they suggested that the symptoms might not be entirely central in origin. Comparative studies had shown that the virus of enzoötic encephalomyelitis was disseminated in the animal organism like the virus of rabies, herpes, and poliomyelitis. Even in mild degrees Borna disease had a high mortality, and animals which recovered from one attack were not thereby rendered immune to a second one. It was not clear whether the second attack was due to reinfection or to a persistence of the first infection. Attempts had been made in rabbits to shorten the incubation period by giving intracerebral inoculations, but they had not been successful. Attempts had also been made to immunise rabbits by using a virus killed by heat, chloroform, carbolic acid or glycerin; but again without success. A formalised vaccine inoculated subdurally, with a second dose several days later, had protected 3 out of 11 animals (rabbits and monkeys).

Mr. Galloway also gave an account of the disease called paralysis of fowls, a specific condition described in Germany, America, and Holland, which he had recently found in this country. Among the symptoms were a partial and progressive paralysis of the wings and legs, sometimes associated with ocular disturbance, and these facts suggested that it was due to infection. In this disease also the chief pathological changes were found in the nervous system. In the peripheral nerves the essential feature seemed to be an intense infiltration with lymphoid plasma cells and large mononuclears. In some of the cases the whole nerve tissue seemed to be replaced by the infiltrating cells—an infiltration so intense as to be unequalled in any other encephalomyelitis. The myelin sheaths degenerated secondarily as a result of the infiltration. Similar infiltrations, chiefly vascular, were found in the brain, cord, and meninges, and also in the spinal ganglia. The disease could be transmitted to other chickens by intracerebral injection of emulsion of the nerve tissues of the paralysed fowls.

Dr. J. G. GREENFIELD said that from the pathological point of view there seemed to be three main groups of encephalomyelitis—those due to visible organisms, those due to a distinct species of neurotropic virus, and those which followed infective fevers. In the first of these groups the inflammatory process in the nervous system resembled that in other organs, except that nervous tissue seemed to be particularly vulnerable. Inflammation was found to be either focal or more diffuse according to the extent of distribution of the organism and the patient's power of resistance. The second group included encephalitis lethargica, Borna disease, rabies, and the herpes encephalitis found in rabbits. Here the virus was diffused throughout the nervous system, though it primarily attacked the neuron, probably by invading the nerve cell. Sometimes the nerve reacted by forming special structures, such as Negri bodies. Certain parts of the nervous system seemed to be especially liable to attack; examples were the selection of the substantia nigra in encephalitis lethargica and the hippocampus in rabies. The cases in the third class were characterised pathologically by focal demyelination without destruction of neurons, the foci being chiefly round vessels, along the walls of the ventricles, and round the margin of the cord.

Dr. W. RUSSELL BRAIN drew attention to an insufficiently recognised group of cases which had been tentatively described as acute infective encephalopathies. They comprised cases in which acute or subacute cerebral symptoms were produced by a toxæmia resulting from infection without the infecting agent being in the nervous system. Three clinical groups could be recognised: (1) those in which the symptoms were exclusively or mainly meningeal; (2) those in which there were both meningeal or cerebral and spinal symptoms; and (3) those having spinal symptoms without cerebral.

Prof. TOM HARE spoke of distemper and other diseases in dogs, and Mr. LESLIE PUGH gave a short account of work in connexion with a specific encephalomyelitis of the dog, independent of distemper.

MEDICAL WOMEN'S INTERNATIONAL ASSOCIATION.—This Association is holding its quinquennial meeting in Paris from April 10th to 15th, and it is expected that representatives from some 20 countries will attend. Beside the Council and general meetings there will be three scientific sessions on the afternoons of April 11th–13th, which will be open to all medical women. The subjects for discussion will be Sex Instruction for Children and Adolescents and Analgesia in Midwifery. The programme of social activities includes a reception given by the President of the French Senate at the Palais du Luxembourg, and another by the President of the Municipal Council at the Hôtel de Ville. Special arrangements have also been made for visiting the Radium and Pasteur Institutes, as well as several of the most notable hospitals of Paris. Further information may be had from the hon. secretary, Dr. L. Martindale, 28, Weymouth-street, London, W. 1.

---

* Prof. James McIntosh lately stated in our columns (THE LANCET, 1928, ii., 1051) that he had found signs of the disease in a pony which developed it in the Island of Skye.—ED. L.

Reviews and Notices of Books.

MEDICAL HISTORY OF CANADA.

Four Centuries of Medical History in Canada and a Sketch of the Medical History of Newfoundland. By JOHN J. HEAGERTY, M.D., D.P.H. Bristol: John Wright and Sons, Ltd. 1928. In 2 vols., pp. 395 and 374 respectively. 50*s.*

Dr. J. J. Heagerty who is attached to the Canadian Department of Health, is to be thoroughly congratulated upon a valuable work, the title of which does little to convey the range and interest of the contents. Learning as well as industry have gone to the compilation of this record, for the volume is not only a survey of the medical history of Canada since the days of Francis I. of France and Jacques Cartier, but it provides a vivid picture of the medicine, surgery, and public health of the provinces and cities as they have developed, describing the whole machinery of sanitary government in the Dominion, while dealing fully with the epidemic diseases as they have been known to occur since European incursion brought with them their tales of infection.

The section on epidemic diseases with which the first volume commences is a particularly full one, forming a many-sided selection of notes upon the various pestilences against which the strict, and indeed inhuman regulations of quarantine were set up. Few readers would know exactly what to expect in a chapter headed "Ship Fevers," for the words "ship fever" and the popular term "yellow jack" were commonly interchangeable in nautical reports—i.e., "ship fever" was yellow fever. But it is clear from a chapter of lurid interest that under the name "ship fever" were also included typhus, which was particularly fatal to the numerous Irish emigrants of the middle of the nineteenth century, typhoid fever, plague, leprosy, and small-pox. Plague may have been an infrequent guest on board even the miserably ill-found vessels of the eighteenth century, but some of the records that are quoted show that it certainly did occur, the usual story being that the ship had departed from Marseilles where plague was ever rife to make for the important French settlement of Quebec. It seems that while in certain old records yellow fever and plague appear to have been used as identical terms, the differentiation between plague and small-pox was also quite hazy, and the symptoms of each might and probably were attributed to syphilis. An interesting chapter deals with "Mal de la Baie St-Paul" which is described at considerable length without any exact conclusion being come to as to its nature. The greater number of the symptoms could be accounted for on the supposition that the patients were the victims of syphilis disseminated extra-congenitally, but syphilis of a form with which we are to-day not familiar.

The distinctly clinical section of epidemiology is followed instead of preceded by a section describing the pioneer physicians of Canada, the early medical journals, the early scientific societies, and the development of public health departments. This section is completed in the second volume, the rest of which is made up of the history and descriptions of the medical schools and hospitals of the Dominion, while the story as it occurred in Newfoundland appears in an appendix.

The information upon medical journalism will be informing to the increasing number of practitioners who take an interest in the development of medical literature. The first medical journal published in Canada—namely, the *Quebec Medical Journal*—appeared in 1826, and had among its editors the founder, Dr. Xavier Tessier, and a committee among whom were the Quebec physicians Joseph Painchaud, Joseph Parent, Joseph Morrin, François Blanchet, C. N. Perrault, P. M. Bardy, and W. A. Hall, and the Montreal physicians Caldwell, William Robertson, and John Stephenson. The large element of French thought continued to be represented much later when the *Dominion Medical Journal* was published in Toronto for the first time in the city of Toronto in the year 1868, the *Lancette Canadienne*, the French medical journal of Montreal having disappeared some 20 years earlier. Then in the year 1872 came the *Canadian Medical Record* of Montreal, the *Canadian Medical and Surgical Journal* of Montreal, and *l'Union Médicale du Canada* also of Montreal. *L'Union Médicale du Canada* was in the beginning a quarterly but later was published as a monthly when it was known as the *Revue Mensuelle de Médecine et Chirurgie*. It is still being published. The more modern developments of medical journalism in Canada need not be recapitulated, but their origins and provenence are fully set out and form a curious bibliographical note.

No purpose would be served by a summary survey of the pages of these handsome volumes; the work is eminently readable as well as worth reading, and we commend it to readers for their study. The lessons in medical politics to be derived, almost unconsciously, from historic records of this sort are often of unexpected aptness.

DISEASES OF THE LIVER, GALL-BLADDER, AND BILE-DUCTS.

Third edition. By Sir HUMPHRY ROLLESTON, Bart., K.C.B., M.D., Hon. D.Sc., D.C.L., LL.D., Regius Professor of Physic in the University of Cambridge; Emeritus Physician, St. George's Hospital; Sometime President of the Royal College of Physicians of London; and JOHN WILLIAM MCNEE, D.S.O., M.D., D.Sc., F.R.C.P., Associate Physician to University College Hospital. Illustrated. London: Macmillan and Co., Ltd. 1929. Pp. 884. 42*s.*

SINCE the second edition of this book was published in 1912 many advances in the subject have been made which have necessitated considerable additions. Particularly is this true with regard to jaundice. The subject is approached with a review of the more important recent experimental advances, and a statement of the present theories and known facts of the physiology of bile-pigment and bile-acid formation. A discussion follows of the van den Bergh reaction, the technique of which is given in an appendix at the end of the book, and the influence that this test has had on the classification of various types of jaundice into obstructive hepatic jaundice, toxic and infective hepatic jaundice, and hæmolytic jaundice. "Catarrhal" jaundice is placed in the second group, and the view is expressed that it is due to an infection involving both bile-ducts and liver cells rather than to an obstruction at the lower end of the common bile-duct, as was suggested by Virchow.

In the chapter on tests for hepatic function due emphasis is laid upon the fact that the multiplicity of reactions controlled by the liver makes it impossible to estimate the efficiency of the organ as a whole by chemical methods, which are chosen to test quantitatively some single function of the organ. If the lævulose test shows impaired carbohydrate function, it does not follow that the action of the liver on proteins is also impaired. The various tests for hepatic efficiency are therefore discussed in relation to the specific metabolic activity that they are designed to test. They include tests depending on the excretion of dyes by the liver, on carbohydrate, fat, and protein metabolism, on the formation of fibrinogen, on the detoxifying power of the liver, the Widal hæmoclasic function, and the biliary function. The technique and value of each test are briefly discussed. The radiological diagnosis of diseases of the biliary tract are well described, with a brief history of the development of the technique now practised, and the methods of administration and value in X ray diagnosis of iodine and bromine compounds. The ample references in the text and excellent index add to the value of this work. Many accounts of actual cases are given, and 54 fresh illustrations have been added.

The whole book is up to date, and provides a complete account of present knowledge of diseases of the liver and its appendages.

Surgery of Joints.

Die Chirurgie der Gelenke und Schleimbeutel. By Profs. E. Seifert, E. Stahnke, Med. Rat. Prof. F. König, all of Würzburg. Berlin and Vienna: Urban and Schwarzenberg. 1928. Pp. 315. M.20.

This instalment of a work designed on an encyclopædic scale is not unworthy of its foregoers. It is fasciculus 23 of Vol. II. of the second part of "Die Chirurgie," a comprehensive presentation of general and special surgery edited by Prof. Dr. M. Kirschner, of Tübingen, and Prof. Dr. O. Nordmann, of Berlin. Its authors show a tendency to lay more stress upon rarities and novelties than on the everyday subjects of surgical work and demonstration. For instance, we find that four pages and a coloured plate are devoted to Kienbock's disease of the semilunar bone of the wrist, whereas gonorrhœal arthritis gets just three. On the whole this fasciculus, despite its size, gives us the impression of treating its subject matter in a sketchy manner. Eight pages only are given up to a discussion of tuberculous disease of the hip. Section A of this fasciculus treats of the surgery of joints, excluding tuberculosis; Section B of tuberculosis of joints, and Section C, which consists of only six pages, deals with surgical diseases of bursæ.

The volume contains no details of treatment, only a very few illustrations of appliances, no descriptions of operations, and no discussion of the best ways of treating chronic joint disease. Osteo-arthritis, which is known in Germany as arthritis deformans, receives the fullest consideration among non-tuberculous lesions, but what is distinguished in this country as rheumatoid arthritis is passed over cursorily.

Perhaps the details of treatment will receive full consideration in another fasciculus, but we have failed to find any mention of such a one in the prospectus of the work as advertised on the cover.

Comparative Anatomy.

The Frog. Twelfth edition. By the late A. Milnes Marshall. Edited by H. G. Newth. London: Macmillan and Co. 1928. Pp. 182. With 40 figures. 6*s.*

It is a pleasure to see yet another improved edition of this incomparable "introduction to anatomy, histology, and embryology." Since 1882 it has guided innumerable students into the true faith, and its solid soundness will, we hope, carry it on indefinitely as a very good book. Mr. Newth's alterations and improvements are conceived in the right spirit of respect for a tradition which ought to be maintained. A brief account of the original author, with perhaps a portrait, would be an improvement.

Contributions to the Principles of Morphology. By W. B. Crow. London: Kegan Paul, Trench, Trübner and Co., Ltd. 1929. Pp. 94. 5*s.*

An interesting quiet essay, approved as a thesis for the degree of D.Sc. Lond., on the general ideas underlying our conceptions of individuality, classification, and phylogeny, treated historically. It will be a useful help to orderly thought.

The Principles of Applied Zoology.

By R. A. Wardle, Professor of Zoology in the University of Manitoba. London: Longmans, Green and Co., Ltd. 1929. Pp. 427. With 55 text figures. 21*s.*

By "principles" Prof. Wardle means "elements," and no one need be afraid of finding here a philosophical treatise on fundamental conceptions. The book is just an amazing mass of well-arranged facts (or near-facts) of quite unusual interest which come under the common head of relating zoology to human affairs. Part I. deals with medical and veterinary zoology—protozoa, worms, and insects in relation to disease. Part II., on agricultural and horticultural zoology, contains chapters on insect pests (as one would expect from the author, very thoroughly prepared), vermin, bird encouragement, livestock and their breeding. Most readers other than hard-pressed students will probably find the account of animal industries in Part III. the most entertaining: bees, silkworms, fisheries, whaling, and a long account of the fur industry. There is a close-printed bibliography of 27 pages. The book appeals to so many interests that it ought to be widely popular—how to avoid malaria, how to kill caterpillars, and how to choose your wife a fur coat (the synonymy of the fur trade is remarkable) are seldom described in the same volume. We congratulate Prof. Wardle on having added the best to the series of good books which he has written.

Artificial Pneumothorax.

Essai sur le pneumothorax artificiel bilatéral et simultané. By Dr. Jean Terrasse. Paris: Louis Arnette. 1928. Pp. 116 and plates. Fr.45.

The number of books on collapse therapy of the tuberculous lung is legion. This book breaks no new ground; it is a short and lucid exposition of the reasons for applying the method of artificial pneumothorax, its risks, its effects on diseased and sound lung, and the complications which may ensue. Considerable space is devoted to bilateral artificial pneumothorax both by the method of collapsing one lung and later the other, and by the method of simultaneous partial collapse with small quantities of air. Oleothorax is mentioned in passing, but very little space is devoted to all the accessory operations which have now grown up around the original pneumothorax technique. There is no description of various types of apparatus. Quite half the space in the book is taken up with descriptions of cases with temperature charts, radiograms, and chest diagrams, a method of exposition which is apt to become tedious to those who have not seen the patients. The book contains a useful short bibliography. We are glad to note that the author emphasises the importance of the general hygienic treatment, with adequate periods of rest, of patients undergoing treatment by artificial pneumothorax. Without this precaution the whole benefit of the method is lost.

Practical Bacteriology.

By Fred W. Tanner, Ph.D., Professor of Bacteriology and Head of the Department, University of Illinois. New York: John Wiley and Sons, Inc.; London: Chapman and Hall, Ltd. 1928. Pp. 235. 12*s.* 6*d.*

This book is a companion volume to the author's "Bacteriology," and has been designed so as to introduce students to bacteriology as a pure science and not necessarily or solely to the examination of pathogenic micro-organisms. A course of actual laboratory classes is outlined, and the way in which it can be carried out thoroughly is indicated. The student is told the value of an intimate knowledge of his tools and descriptions follow of the microscope and how to use it; of glassware and its toilet; of the preparation of media, and of cotton-wool plugging. Most of the usual methods are adequately dealt with but fuller details of filters might have been included, and it seems a loss that the final advantage of the McIntosh-Fildes anaerobic jar was not added to the account of the Novy jars. In the section on stains no distinction is made between acid-fast and acid-alcohol-fast bacteria. Five pages are devoted to the Gram stain, yet no formula for the original method has been given. Some American modifications only have been set out, and it is noteworthy that whereas all descriptions of the original Gram expressly preclude washing with water, the methods here advocated allow it.

This practical course has been conceived on original lines and should achieve the author's purpose of widening the study of bacteria and fungi.

THE LANCET.

LONDON: SATURDAY, APRIL 6, 1929.

GASTRIC SECRETION.

HE secretion of the stomach plays an important ; in human economy, and many are the functions :h have been attributed to it. The gastric juice luces physical changes in the contents of the us, bringing them to body temperature and icing them to a fluid or semi-fluid state suitable passing on into the intestine ; it acts chemically any of the substances of the food, reducing native eins to albumoses and peptones, and changing inogen to casein. Fat, too, is partly digested he stomach by means of a fat-splitting ferment. sted food is to a certain extent sterilised by the ochloric acid of the juice, while the mucus ed out by the surface epithelium protects the g membrane of the whole tract from the action rritant substances. Gastric secretion exercises mportant function in the body by influencing the -base equilibrium ; it has even been suggested the stomach may at times act as an excretory n in ridding the body of toxic substances, as in remesis gravidarum. Our knowledge of the ic secretion has been obtained partly by means *periments on animals, partly from observations* atients with gastric fistula, and more recently stomach contents of patients have been with- n at intervals after giving a test-meal of varied osition, chemical analyses being made of the eeds. The experimental methods of observing gastric secretion in animals were initiated in 8 by Heidenhain, who artificially isolated a ion of the fundus of a dog's stomach from the of the organ, and were elaborated by Pavlov is pupils at the end of the century. Pavlov entiated three phases of gastric secretion in the In the first phase, the sight or smell of food, chewing of food in the mouth even though llowed, led to a considerable secretion of gastric through the vagi nerves. A second phase d as the result of the chemical stimulus of digested foods acting on the mucous membrane pyloric antrum ; it was thought at one time he resultant effect on the secretory glands of ndus of the stomach was brought about by agastric reflex through the intrinsic nervous s of the stomach, but it is now believed that nulus is carried by the blood in the form of a y hormone, the gastric secretin first described INS. A third stage is that brought about nical stimuli of food products in the duodenum all intestine ; this phase, though not intense, long continued. The first or psychic phase e which specially interested Pavlov and led to the remarkable researches in experimental gy which have occupied his later years. The experiments were continued, however, by s and assistants, and a considerable literature n up on the subject, which has been dignified name of the science of chymology. Pavlov's sistants, B. P. Babkin and E. S. London, lected the results, which show that the of foods and their evacuation from the are controlled by a remarkable series of and motor involuntary reflexes

Carefully devised experiments on healthy dogs, in which, by means of fistulæ, the material from gullet, stomach, duodenum, and gall-bladder can be obtained in pure state, have enabled the complicated processes of digestion to be dissected into their elements. It is found that what appear to be intricate physiological phenomena can be reduced in essence to a close approximation to simple physico-chemical laws. Given the right conditions, the stomach has the character of a test-tube, in which the course of digestion of minced meat, for example, is found to follow a logarithmic curve showing the closest approximation to a theoretical curve laid down by S. Arrhenius for digestive ferment action ; while a starch meal solution, which is unaltered in the dog's stomach, is passed on into the duodenum at a rate conforming to a simple monomolecular formula. Moreover, the quantity of gastric secretion is proportional to the square root of the quantity of food ingested, while the duration of digestion or the length of time taken to evacuate the stomach is also proportional to the square root of the quantity of food ingested into the stomach. That is to say, the quantity of secretion and the time of digestion are found to bear a very simple quantitative relationship to the amount of food. The course of digestion for meat and fats was determined—starch is not digested in the dog's stomach—and it was found that in a mixture of foodstuffs each follows its own course of digestion, so that the digestion of milk which contains all three could be dissected into a series of separate processes affecting each of the constituents independently. A mixture of foods makes the analysis more difficult but not impracticable. In man, however, it was soon found that an analysis of the stomach contents on a mixed diet was too complicated to afford useful information, and various types of test-meal were introduced. In these a food or simple mixture of foods is given, and after a specified time or at intervals a portion or the whole of the remaining stomach contents is removed. The older test-meals of Ewald and Boas gave useful information about the gross secretion of hydrochloric acid and pepsin, but necessarily represented the static position which the digestive process had reached in the time allowed. As the chemistry of the stomach is constantly altering, the newer methods have aimed rather at giving an estimate of the kinetics of the processes involved. The substances used in test-meals have become simpler and more indifferent, while fractional portions of the stomach contents removed at intervals afford material for analysis of a series of stages of digestion. The test-meal introduced by Rehfuss in 1914 is now used widely in the United States and in this country. In Germany preference is given to the alcohol test-meal of Ehrmann, or a plain meal of water containing pure caffein devised by Katsch. Such simple test-meals, containing no protein or salts, are recommended because of the ease of determination of the true acidity, for this is only approximately assessed by titration methods in the presence of buffering substances like proteins and salts.

The interpretation of the test-meal results has given rise to a good deal of controversy. Considerable variations occur without being outside normal physiological limits, but certain types of result are almost characteristic of certain types of stomach. Even in a number of apparently healthy people hydrochloric acid is entirely absent throughout the digestive process ; Bennett and Ryle[1] found 4 per cent. of a series of normal people to be achlorhydric. In others acid secretion is more active than the average. Hurst, who has contributed so much to the advance of knowledge of the clinical physiology and pathology of digestion in this country, holds that in many instances these features are inherent in the make-up of the individual, and are in the nature of inborn errors of secretion.[2] According to this view, there is on the one hand a congenital over-secretion of hydrochloric acid by the stomach, a veritable gastric-ulcer diathesis; while in other cases there is a true achylia gastrica of constitutional origin. Faber[3] holds that a condition of preceding gastritis underlies both the variations in hydrochloric acid secretion and the origin of ulcer. Special importance is given to a localised gastritis of the pyloric region, which may give rise to the pyloric syndrome, involving alterations both in the acid secretion and in the emptying of the stomach. From estimating the total chlorides, inorganic chlorides, and free hydrochloric acid or active chlorides, Bolton and Goodhart[4] came to the conclusion that the acidity was neutralised towards the end of digestion by a reflux of strongly alkaline pancreatic juice. This process of regurgitation of duodenal contents had been observed by Boldyreff in animals, who found that it regulates the gastric acidity and that hyperacidity is generally due to defective neutralisation. Pavlov had observed that some neutralisation of the hydrochloric acid takes place by the mucus secreted by the stomach wall. The idea has been put forward by MacLean[5] that the stomach automatically regulates the hydrogen-ion concentration of its contents, and that at a stage of digestion pepsin ferment may continue to be secreted by the stomach wall in the presence of neutral chlorides. In the natural process digestion comes to a standstill by the action of extragastric inhibitory nerves. It may well be that the problems of gastric secretion and digestion in the human stomach will yield to inquiry, and that in man also time will show that the results can be stated in terms of physico-chemical laws, but much work remains to be done before this can be realised.

◆

THE POWERS OF THE POLICE.

The Royal Commission on Police Powers and Procedure, presided over by Lord Lee, has discharged the first duty of a Royal Commission by producing a unanimous report.[6] Points of special interest to the medical profession are few. Fatigue in witnesses was considered. There have been criticisms that the police, when taking statements, as in Miss Savidge's case, prolong the examination unduly in order to extract admissions by mere exhaustion. The Howard League of Penal Reform proposed a time limit of five hours (with an interval)—the length of a normal court session. The Royal Commission deprecates any time limit; unless fixed absurdly low, a rigid limit would be too long for some people and unnecessarily short for others; moreover, the very existence of a limit might not only lead the police to be careless in watching for signs of fatigue but might even encourage a policeman to press his questions unduly as the end of the period approached. The police, says the report, should watch the deponent for any signs of exhaustion and should offer a break (with or without refreshment) at suitable intervals, or even a postponement to the next day; nor should the witness be asked to sign a statement at the end of a long and tiring interview; ample time should be allowed for careful study before signature. A question on which members of the medical profession will be capable of forming a conclusion is whether statements from women and children in sexual cases should be taken by men or women. The Bridgeman Committee on the Employment of Policewomen recommended in 1924 that, so far as practicable, arrangements be made everywhere for the taking of such statements by policewomen. The Departmental Committee on Sexual Offences against Young Persons spoke, in 1925, of the fact that parents and teachers report offences more readily when they know that a girl will make her statement to a woman. That Committee was impressed by the general evidence that many girls suffer from shock as a result of these offences and that further distress is lessened if, in the first instance, the story is told to a woman. Lord Lee's Commission agrees that a sufficient number of qualified and specially trained women should be made available to take statements from all young girls and children in sexual cases. The report suggests that the women thus selected need not be attested policewomen; when it goes on to say that they should be of high character, suitable temperament, good education, and adequate training, it seems to offer prospects of useful and responsible employment to women who have taken medical degrees. The Royal Commission is dissatisfied with the present compromise under which, when a suitable woman is not available, the statement is taken by a male officer in the presence of a second woman. The latter is present in part, it appears, to protect the policeman from subsequent accusation, but the Commission regards this mixed audience as being, from the point of view of the person making the statement, "the worst possible arrangement and the most embarrassing which could be devised for the narration of the details of some sexual offence." The report has a good deal more to say on the employment of policewomen, on the understaffing of the police force, on the duties of the Director of Public Prosecutions, on cautioning suspects, on agents provocateurs, and other matters. In training the police the aim should be, says the Royal Commission in a medical metaphor, the production of "general practitioners" rather than of specialists.

There are some healthy observations on the difficulties of the police, and the consequent danger to the good relations between police and public, where the police are called upon to enforce laws which are out of harmony with public opinion. These disputable offences are refreshingly summed up, and the clarification of the law is demanded. There is street betting where public opinion is tolerant and the police must expect more hindrance than help. There is the dubious law of lotteries; the local diversity of policy towards whist drives leads the Commission to suggest that the Home Office should make up its mind and issue clear instructions. There are also the offences against public decency and street offences like solicitation. Private citizens are reluctant to complain of "annoyance," and thus the cases come to be decided on police evidence alone. The defence usually involves attacking the police, and, while one section of the public complains that the policeman is too busy, another complains that he is too inactive and hints at connivances due to corruption. All the while the energies of the police are being increasingly diverted to many miscellaneous duties outside their primary function of preventing and detecting crime. They are engrossed with motor traffic and with many new offences which bring the law-abiding citizen for the first time into an unaccustomed conflict with the law and consequently cause a state of friction. The Commission finds it significant that many complaints have proved to be directed not so much against the policeman as against the laws which he has to enforce. Far the most frequent allegations of dishonesty against the police appear to concern offences which, though infringements of the law, are not popularly regarded as morally reprehensible. In criticising the excessive zeal of certain chief constables, the report has a sentence worth quoting: "In our view a grave responsibility rests on those who create criminal offences which are not precisely or clearly defined, or in respect of which the requisite evidence to support a conviction cannot be obtained by straightforward and unequivocal methods."

The Royal Commission was not empowered to take evidence on oath, so did not investigate the truth or falsity of allegations and counter-statements in particular cases, but it has made a searching examination into police administration. The English policeman emerges with his high reputation unshaken. In particular, no creditable proof has been found of the use of "third degree" methods. As an illustration of the lengths to which such methods may be carried in other lands, an appendix to the report reprints from THE LANCET [7] an article on Cross Examination under Anæsthetic, in which we recounted last year an attempt at Hawaii to extract a confession of murder by means of an injection of hyoscine.

ECONOMICS OF THE NURSE'S TRAINING.

SCIENCE cannot save lives or cure disease until it is applied, and to a large degree the application of medical science is through the art of nursing, and its ultimate success rests on the full development of this art. Some understanding of the scientific principles underlying the art of nursing is essential, and for the safety of the public the State has prescribed a minimum standard of knowledge and training before granting the title of nurse. But what is suffering at present is the art of nursing, since hospitals have now accepted the dual task of nursing the sick and educating the nurse where formerly many of them only recognised their obligation to do the former. Satisfactorily to fulfil both obligations might involve doubling the staff with a proportionate increase in administrative expenditure, a financial burden which would be unbearable under the present system. And yet both obligations must be fulfilled if hospitals are to prosper as they should, and this will mean, as Dr. E. C. HADLEY points out in a thoughtful contribution to the *Nursing Times*, the passing of the present transitional period in the history of the nursing profession. No nurse can become efficient in her art without continued practice in actual bedside nursing under skilled supervision which should never be relaxed. But the breathless rush of routine within our hospitals to-day is not consistent with any of the underlying principles of nursing and leaves practically no margin of time for organised and efficient bedside instruction. The responsibilities of a ward sister to the medical and administrative staff are too engrossing for her to fulfil her other duties as an instructor of nurses. Nor is the student nurse under the present regime in a fit state, physically and mentally, to benefit by her instruction.

And why? Her time is now occupied (we reproduce Dr. HADLEY'S list) with: cleaning, sweeping, and polishing floors in wards and adjacent rooms; scrubbing shelves, cupboards, lockers, sinks, and sluices; polishing taps and brasses; lifting beds about, not simply empty beds but often with the patient; mending and patching garments and other sewing jobs; washing up crockery, pots and pans, tea urns. But, as he remarks, the student nurse has plenty to do and to learn without doing work that belongs to a labourer or house porter, ward maid or charwoman, seamstress or domestic servant. Probationer nurses have come to do this work because their labour can be bought cheaply, although not now so cheaply as in the past. The problem of nursing education is essentially an economic one. A nurse cannot become skilled without the actual performance of services and it is for the hospital to determine fairly what those services are worth in the terms of the labour market. We think it safe to predict that when this is done the nurse will be found to be paying in service more than the equivalent of what she receives in education and training. It is manifestly unfair to the student nurse to demand from her service which does not tend to develop her skill and this is what many hospitals are doing. The solution will be found in the endowment of training schools or by adequate grants for training from the Board of Education. To educate the nurse both in the science and art of nursing should prove to be a good investment both for the public and for the medical profession, but until nurses themselves awake to the potentialities of their calling and demand the right conditions for the practice of their art, as the medical profession has done before them, the problem will remain unsolved. What these potentialities are has scarcely even been explored. The value of Dr. HADLEY'S article lies in his vivid realisation of the value to medicine of the properly trained nurse. We agree with him that her training and education merit the same care and consideration which is given to those of a medical student.

Annotations.

"Ne quid nimis."

THE KING.

WE published in THE LANCET of March 23rd the official bulletin issued from Craigweil House on March 16th. Another bulletin was issued from the same residence in the evening of Friday, March 29th, as follows:—"His Majesty the King continues to make satisfactory progress in spite of tiresome rheumatism round the right shoulder. Weight is increasing, appetite is returning, sleep is of better quality. The insistence on a lengthy abstention from all but essential public duties and a quiet life in the present suitable climate is being justified in the steady improvement in His Majesty's bodily and mental vigour." The bulletin was signed by Sir Stanley Hewett and Lord Dawson of Penn.

THE PREVALENCE OF SPINAL IRREGULARITIES

A PAPER lately published by B. C. Cushway and R. J. Maier [1] is of considerable interest to anatomists and to surgeons, especially those engaged in industrial practice. Under the title of Routine Examination of the Spine for Industrial Employees they record their findings in the radiological examination of the spines of 031 men who applied for work as switchmen and firemen on the Belt Railroad, Chicago. These men had previously passed a rigid preliminary physical examination without any visible anatomical variations or disturbance in function being found.

---

[7] THE LANCET, 1928, ii., 990.

[1] Jour. Amer. Med. Assoc., March 2nd, p. 693.

and none of them was aware of anything wrong with the spine. The primary object of the inquiry was medico-legal; it was intended to protect the *employer from subsequent claims for compensation* after injury, based upon radiographic evidence of spinal abnormality which might have existed before, and have nothing to do with the injury in question. When such a claim is made it is manifestly impossible for the expert witness to say how long the abnormality as shown on the radiogram has been present, and often he cannot decide whether it is ante- or post-traumatic. Variations from what osteologists describe as the normal anatomy of the spine are very often met with; they may affect not only the form but the number of the vertebræ. But we were not prepared to learn, as we do from this paper, that out of 931 cases as many as 414, or over 45 per cent., showed some congenital abnormality, the total number of variations from normal being 605. It is surprising to find that 81 cases of scoliosis and 13 of tuberculosis, as well as some cases of old fracture of ribs, vertebræ, and pelvis had escaped detection by the rigid preliminary physical examination. The total number of congenital and developmental anomalies recorded was 510. The commonest developmental defect was a partial failure of the two lateral halves of the column to unite in the middle line, constituting spina bifida occulta. This condition was found in 161 cases. We are not told whether in any of them there were any clinical signs of spina bifida. Proliferative changes such as arthritis or calcification of the ilio-lumbar ligament were recorded in a considerable number of cases. No statement is made of the ages of the subjects of this inquiry, but presumably some of them had reached middle age when so-called rheumatic troubles might be expected. The observations are very interesting, but their value for us is diminished by lack of data for comparison of the conditions of employment in the United States and in Great Britain. It appears, however, that just as complaints of pain in the lower back seem to be commoner in the "white collar" classes in America, so complaints of injury to the back are relatively numerous among workers in factories and railroads and the like. Be that as it may, it is clear that a record of the condition of every workman's spine at the time of his engagement must be of great value in determining claims for compensation in the event of his being injured afterwards. The taking, examining, classifying, and storing of radiograms must be an expensive business, however, and is only justifiable when workmen are engaged for more than a short time. It would be impracticable for casual labourers. The authors' statement that each individual "may be identified by a rontgenogram of the spine just as definitely as by a photograph of the face or by finger-prints" strikes us as somewhat hyperbolical in the present state of radiography, at any rate as regards ease of identification. They themselves admit that they found it very hard at first to distinguish the normal from the abnormal, largely because of uncertainty about what should be considered normal.

OPIUM IN CHILDHOOD.

OPINION is sharply divided upon the use of opium in therapeutics, and nowhere is this difference of opinion so marked as where it concerns the use of the drug in the diseases of childhood. Sydenham and, later, Charles West urged the calming properties of opium and its derivatives, but Trousseau, in particular, emphasised the dangers of the drug with his statement that in breast-fed infants half a drop of laudanum in the course of 24 hours might produce symptoms of severe narcosis. Whatever may be said on this side, opium is too valuable a drug to be lightly abandoned in pædiatric practice, and it is interesting to read a paper in which G. Blechmann and P. Delthil[1] discuss how and when it should be employed. In the first place, they remark that most of the accidents following the administration of opium have been in cases where laudanum was used, and they believe that the child is better able to tolerate *the isolated alkaloids than complex preparations such* as laudanum. Moreover, the condition of the child is important, and it is well known that a dose that would be poisonous to a normal child is well tolerated by the sick child who is in pain. These writers believe that most of the dangers attendant upon the use of opium in childhood can be obviated if the drug is taken freely diluted and if the dose is spread out over 24 hours. As regards the form in which it should be given, they observe that laudanum has always been popular, and if the above simple rules are observed, then a dosage of two to three drops per year of age should be considered as normal. Paregoric provides a convenient way of giving more dilute doses of the drug, and Dover's powder is regarded as an excellent preparation, especially for pulmonary disorders, where its sedative action is counterbalanced by the expectorant effect of the ipecacuanha. If morphia is to be employed it must be well diluted, and it is recommended that a 1 in 1000 solution should be used for the infant, and in this way 1·5–2·0 mg. of morphia per year of age in divided doses may be administered. (This is equivalant to approximately gr. 1/40 to 1/32. The official B.P. injection of morphia is a 1 in 40 solution of the tartrate.) Papaverine is a preparation very little used in this country, but in view of its selective action on unstriated muscle it is recommended for such conditions as asthma and whooping-cough. As to the indications for the use of opium, the severely painful colics calling for such a powerful sedative are not so common in children as in adults. Certain spasmodic conditions, however, do occur, and Blechmann and Delthil mention in particular laryngeal spasm. Injections of morphia for these troublesome conditions they consider remarkably effective, but an adequate dose must be employed. In asthma, on the other hand, they think opium should not be used in children except for the occasional exhibition of Dover's powder for troublesome catarrhal attacks. In this connexion they discuss the question of opium in diseased conditions of the respiratory system, pointing out that while the drug certainly calms an irritating cough it must be remembered that the cough may be essential if the child is to clear its inflamed bronchi. Hence the type of cough must be carefully considered, and if opium is to be used, then Dover's powder is the best form. Probably the most important uses of opium in childhood are in diseases of the alimentary system, and it is just here that opinion is so divided. Opium has a triple action on the digestive tract; it reduces peristalsis, diminishes secretion, and calms painful conditions. There are certain disorders in infancy where it is extremely valuable. A type of diarrhœa with excessive peristalsis after each meal, with attacks of colic and sometimes vomiting, due apparently to irritation of the bowel, often yields to opium and nothing else. On the other hand, in the infective diarrhœas opium is almost prohibited, at any rate during the acute stages, although later on, as diet is gradually returning to normal, opium may be very helpful in aiding the infant to regain tolerance for foodstuffs.

In summing up their views the authors of this lucid review insist that opium is too valuable a drug to fall into disuse. They emphasise that the indications for its administration must be clearly appreciated and that safety lies in diluted preparations in which the quantity needed to produce the required result is divided over several doses.

FATIGUE AND EXHAUSTION.

MUSCULAR fatigue has had much attention from physiologists and a good deal of light has been thrown on it of late. But the state of mental or "nervous" exhaustion with which all clinicians are familiar, and which many dismiss as "neurasthenia," is still for the most part unexplained. We are apt to attribute states of nervous exhaustion to severe mental or emotional stress—psychic trauma—and to rely upon subjective symptoms as the sole guide to the degree of fatigue. Attempts to elicit objective signs of nervous exhaustion have met with little success, though clearly any such diagnostic measures, if reliable, must have great clinical value.

---

[1] Rev. de Méd., 1928, No. 8, p. 1061.

Dr. R. D. Gillespie[1] has studied the problem, in a number of patients complaining of severe and persistent fatigue, from the hypothesis that many, if not most, forms of mental illness consist in a state of fatigue and that the symptoms are signs of it. Investigation along clinical lines failed to produce any objective test which was generally applicable. Most authorities agree that the blood pressure tends to be lower and the pulse-rate higher in exhaustion than in good health, and this was the case in Gillespie's patients. The persistently low blood pressure commonly found in post-influenzal debility may be mentioned in this connexion. On the other hand, a low blood pressure and high pulse-rate cannot be regarded as a constant finding in nervous exhaustion. The "lability" of the heart is also thought to be excessive in fatigue, and the changes in pulse-rate and blood pressure when a patient stands up after being recumbent were studied by Gillespie on the basis of Schneider and Truesdell's normal figures obtained from 2000 unselected cases. In the normal there is a slight fall of pulse pressure on getting up, due to a rise of the diastolic and a fall in the systolic pressure. In the fatigued patients examined this fall was found to be almost double the normal; but the pulse-rate for the most part increased no more in the exhausted than in the normal subjects. Examination of the vital capacity, of the basal metabolic rate, and of the reaction to "autonomic" drugs gave no constant abnormality that could be classified as indicative of a state of fatigue. The red blood cell count and the hæmoglobin percentage were equally unprofitable, as is hardly surprising when we remember that many patients with severe primary anæmia are but little fatigued—their state being in striking contrast to the pronounced exhaustion often seen in secondary anæmia where the colour-index is much reduced though the actual anæmia may be far less.

Biochemical tests may offer the most hopeful line of advance, and it is significant that sugar tolerance was diminished in more than a third of Gillespie's patients. Taranowitsch[2] has noted a great increase in organic phosphorus in the urine in prolonged mental work associated with exhaustion; in one case he found nine times as much organic phosphorus in the work period as in the resting condition, though the total phosphate excretion was but little increased. This change in the ratio of organic to inorganic phosphorus excretion is the more interesting when it is remembered how important a part the phosphatides and lipoids play in nervous histology and metabolism. The significance of lactic acid in the blood and excretions is dependent rather upon muscular than upon nervous activity, and the much less intense metabolism of nervous tissue is against the likelihood of any marked changes in the output of this substance in nervous exhaustion. The rôle of the endocrine glands is one which will doubtless become clearer as research continues. The secretion of adrenalin, for example, is increased in states of exhaustion, and this substance is said to be capable experimentally of increasing the capacity of tired muscles to respond to stimuli. The work of Kühl[3] and others has suggested that the cortex of the suprarenal glands may be even more important than adrenalin in protecting the body against exhaustion, and its deficiency may be the essential factor in the extreme collapse of Addison's disease. Bast and collaborators[4] have produced nervous exhaustion in rabbits by preventing sleep and have found conspicuous changes in the suprarenals, especially in the cortex, in 13 out of 14 animals examined. Gillespie, however, does not find that insufficiency of sleep or the presence of focal infections bears more than an associative relationship to feelings of generalised fatigue. This is the more remarkable since the importance of chronic toxæmia is being more fully recognised in the ætiology of many and various pathological conditions. Gonadal hormones are also put forward by some as possibly at fault in nervous exhaustion, and the close association between sexual activities and mental depression and fatigue seems to support this possibility. That emotions—often of sexual origin—may powerfully act on bodily functions is universally recognised; we need only mention the cases of "disordered action of the heart" following war stresses, of hyperthyroidism directly resulting from shock, or the "diarrhœa of fright." Hyperglycæmia, altered coagulability of the blood, and rise of blood pressure are some of the indices that may tell of the degree and extent of emotional stimuli. How far such emotions, if excessive, may cause permanent changes that we may estimate in terms of "fatigue" is as yet unknown; but our knowledge is likely to increase rapidly through further work along biochemical lines and by the search for functional tests of endocrine activity.

ANOXÆMIA IN TUBERCULOSIS.

THE "traditional belief that anoxæmia is never present in pulmonary tuberculosis" has lately been criticised by I. Rappaport,[5] who says that cardiac decompensation as the result of anoxæmia is frequent in phthisis and that expectation of life in this disease depends more on the cardiac condition than on the process in the lungs. The symptoms observed in such complications as spontaneous pneumothorax and severe hæmoptysis are intimately associated, he points out, with a breakdown in the cardiorespiratory mechanism due to anoxæmia. The "anoxæmic cardiac syndrome," with its acute dyspnœa, cyanosis, and distress, is preceded by a stage of slowly progressing anoxæmia of which it is a suddenly aggravated manifestation. Left heart failure is the cause. Spontaneous pneumothorax often passes unnoticed in patients with comparatively sound lungs. When the lungs are already the seat of extensive disease with consequent chronic anoxæmia, a further and sudden reduction of oxygen throws an acute strain on the heart; hence the acute distress. Severe pulmonary hæmorrhage is the commonest cause of acute left heart failure due to anoxæmia. Similarly chronic phthisis frequently presents evidence of a chronic anoxæmic cardiac syndrome manifested by dyspnœa and palpitation. Rappaport says that digitalis, by slowing the heart-rate, may prevent the exhaustion of the compensatory mechanism while morphia, a respiratory depressant, can only do harm. The latter is especially contraindicated, in his opinion, when spontaneous pneumothorax has occurred.

THE INFANCY OF MIDWIFERY.

IN surveying the advances of medical science during the last few hundred years it is impossible to avoid the reflection that many of them are a response to the ills brought by civilisation. One is tempted to include obstetrics in this category, for among primitive peoples childbearing is often so easy as hardly to disturb the mother's working life. Travellers in Africa have reported that Nigerian women, making the pilgrimage to Mecca on foot, will step aside into the forest, give birth to a child, and rejoin the column before the tail of it has passed, their baby slung behind them in the slack of their shawl. The Bedouins afford an example which is at first sight contrary. "The nomad hareem," says Doughty, "are delivered as other mothers, with pangs, after a labour of certain hours. It is a fond opinion that the daughters of the desert are as the wild creatures, that suffer not in childbearing."[1] But the life of Bedouin tribes, outside the imaginings of novelists, is mainly one of under-nutrition, of sloth, and herein perhaps lies the explanation. No advantage is apparent for the pains of childbirth unless they were devised as a warning to seek for cover and quiet that the child may be safely born; and such a warning obviously grows less and less valuable as mankind forsakes the savage life for the slack and sedentary existence of Arab tents and European houses. Yet it seems that the pains of labour have developed only as their use from the evolutionary standpoint became negligible, and we are forced to the conclusion that they are not an inherited burden that once had a "survival value," but rather a penalty incurred by woman when she forsook the outdoor life for the home. Thus it is that historians find little development in obstetrics until the days when town life imposed on women a sedentary and presumably unsuitable existence. Dr. D. G. Madill, whose address on this subject to the Dublin University Biological Society appears in the *Irish Journal of Medical Science* for February, says that one of the first inventions to assist labour was the birth-stool, a horseshoe-shaped seat on four legs with a sloping back. This has been employed in all ages among peoples with some civilisation, and is still in use in the Near East. Dr. Madill thinks that this contrivance marks the transition from an active to a passive attitude in the mother, for many primitive tribes employ devices to enable the parturient woman to bring the maximum voluntary pressure to bear. Hadendoa women, in the Eastern Sudan, stand up and grasp the branch of a tree over their heads; among the Shuli negroes, according to Felkin, the mothers sit on a block with their back to a tree and grasp two upright stakes, fitted with footrests about 18 inches from the ground. Dr. Madill traces the beginnings of obstetrical science among cultivators as opposed to nomads, whom he seems to regard as healthy and active. Erylemana, he says, reports that the North American Indians have their own midwives, and many other peoples hand down obstetrical customs from generation to generation. The earliest of these consist of pressure and kneading of the abdomen, but the midwives of the Pueblos and Indian-born Mexicans along the Pacific coast carry out examinations per vaginam. There is very little record of the extent of obstetrical knowledge in ancient civilisations, and the first details that Dr. Madill quotes are from Greece. Plato remarks that two classes of midwives existed, the higher of which were empowered to administer remedies like medical men and to recite certain hymns during the labour. Herophilus, who lived in Alexandria in the fourth and third centuries B.C., knew how to diagnose pregnancy from the condition of the cervix, and how to distinguish fœtal movements; he instructed women in obstetrics in contravention of the Attic Law, and started the movement which ended in its repeal. Nearly all the midwives in Rome were Greeks, and Soranus (A.D. 100) lays down rules for their qualification, but during the later Roman Empire, according to Dr. Madill, midwifery began to evolve some of the principles which apply to-day. Moschion gave exact details for the artificial rupture of the membranes, and directed that the os should be fully dilated at the onset. Midwives of his day assisted the passage of the placenta by attaching a weight to the cord and making the patient sneeze. Soranus, the foremost obstetrician of the old world, knew of the reposition of prolapsed parts, of artificial dilatation and of craniotomy, and Paulus Aeginatus used a uterine speculum. In the Middle Ages obstetrics had definitely become a science, and many of the forceps, cranitomes, and other instruments exhibited in the Wellcome Museum are almost as effective as those used to-day. The municipality of Freiburg, in Germany, employed four salaried midwives in 1485, and Basle had a school of obstetrical instruction in 1498. In conclusion, Dr. Madill mentions the interesting fact that the Cæsarean section, which from being practised in ancient days fell into disuse among the Romans, was revived by the Christian doctrine of the necessity of baptism as the only barrier to eternal damnation. The earliest record of its performance upon a living woman dates, he says, from 1610, so that its use as a means of saving the mother marks a much later period of enlightenment.

SUPERSENSITIVENESS TO INSULIN.

INSULIN has been but little used in England except in the treatment of diabetes mellitus, but on the Continent it is employed somewhat extensively in other conditions, notably as a *Mastkur* designed to hasten convalescence and increase weight. W. Falta has shown that at least some forms of obesity are probably the result of over-activity of the islets of Langerhans, and there is no doubt that nutrition may often be rapidly improved by artificially increasing the supply of insulin by means of injections, especially when these are associated with administration of glucose. The response to insulin, as measured by estimations of blood-sugar or by the clinical symptoms, is variable in different subjects and in different conditions. In diabetes associated with high blood pressure, or severe cardiac lesions, there is a definite risk of untoward events if dosage is not watched with great care, and fatal collapse may sometimes be caused by amounts that would provoke no such response in an ordinary diabetic. A remarkable sensitiveness is also sometimes apparent when phthisis complicates diabetes, and this may possibly be due to mild protein shock—to which tuberculous patients are especially susceptible—caused by very slight traces of protein present in the injection. In diseases of the liver, such as cirrhosis, very small doses of insulin may produce hypoglycæmia, a fact which is explicable on the assumption that its administration checks the already defective output of sugar from the liver into the blood. This may also account for the supersensitiveness seen in decompensated cardiac cases in which the hepatic function is seriously deranged. In exophthalmic goitre many attempts have been made to prevent the excessive loss of weight by giving insulin and carbohydrate, and very favourable results upon these lines have been reported. It has been thought that hyperthyroidism tends to lessen the activity of insulin, and a much increased sensitiveness to the drug has often been recorded in myxœdema. The extreme resistance to insulin when toxæmia or sepsis is added to diabetes has been attributed to stimulation of the thyroid by septic products, and the glycosuria often found in exophthalmic goitre—especially when this is of toxic origin—is well known. Much experimental work has shown that the thyroid and pancreas are, in fact, antagonistic, and the practical importance of this has led E. Adler[1] to investigate the sensitiveness of patients suffering from hyperthyroidism to small doses of insulin. He has studied the effect of a subcutaneous injection of 5 units upon the blood-sugar in the fasting condition, and has found no apparent difference between the patients examined and a series of normal subjects; nor could any alteration in sensitiveness be noted in relation to the basal metabolic rate or to the severity of the disease as a whole. No increased sensitiveness was obvious as the patient's condition improved, nor could a parallelism be traced between any one symptom and sensitiveness to insulin. These results may set at rest any fears of undue reaction from the use of insulin in Graves's disease, but unfortunately they throw no light upon the fundamental metabolic disturbances of this disorder. This is further evidence of the unhappy truth that insulin has so far done little to reveal the essential pathology of the endocrine organs.

CANCER AND TUBERCULOSIS.

It has often been suggested that there is an inter-relationship between the incidence of cancer and of tuberculosis. Three years ago Dr. Thomas Cherry, of Melbourne, published in our columns [1] the results of a statistical investigation from which he concluded that the incidence of cancer increased as that of tuberculosis diminished, and only a fortnight ago [2] we were able to summarise some remarkable observations by Prof. Raymond Pearl, who found that an organism suffering from active tuberculosis is less often the seat of malignant disease than an organism suffering from other diseases, and, conversely, that tuberculous lesions rarely occur in persons suffering from malignant disease. Dr. Cherry's work has been carried a stage further by extensive experiment on mice.[3] About 100 animals of a given stock were inoculated intracutaneously with tubercle bacilli in small measured doses. Mice are very resistant to tubercle bacilli and the doses given did not produce active tuberculous lesions. A careful post-mortem examination, both macroscopic and microscopic, was made when the animals died, and the results were compared with the cause of death in about 150 control mice of the same stock. A large percentage of the mice, both in the inoculated and in one of the control series, developed lesions in the lymphoid system, such as enlarged lymph glands, lymphoid infiltration of various organs, an enlarged spleen, or a leukæmic blood picture, in various combinations. These lesions are described in considerable detail, and Dr. Cherry seems to attach a degree of importance to them. A disturbing fact which makes the interpretation of the results difficult is that the incidence of these conditions was as high in one of the control batches which had received raw milk in their diet as it was in the inoculated batches. It was much lower in the second control batch which received boiled milk instead of raw milk, and the difference is very naturally attributed to an infection carried by the raw milk. The author seems to incline to the view that these conditions are manifestations of malignancy. That is a view which is open to doubt. Besides these conditions a number of typical malignant new growths were found and the significant fact is that the number was much higher in the inoculated series than in the controls. In the former group six tumours are described as sarcomata—either spindle-celled or mixed-celled—of which two arose at the point of inoculation while the other four were remote from it (abdomen, hind-foot). If the diagnosis is correct the percentage incidence is an abnormally high one, since sarcomata are rare in mice, and no sarcomata were found in the 100 control mice receiving boiled milk. The incidence of carcinomata is even higher, and cases include not only the usual type of neoplasms in the mouse (carcinoma of the mamma and of the leg) but also such unusual examples as carcinomas of the pancreas and of the colon. Although the true malignant nature of some of the tumours does not seem to be fully established either by the description or by the figures accompanying the paper, the experimental evidence submitted establishes a strong case in support of the contention that the experimental inoculation raised the frequency of spontaneous malignant new growths. Dr. Cherry states very clearly that he does not interpret his results as demonstrating a direct specific causal nexus between the tubercle bacillus and malignancy. The relationship is an indirect one. The tubercle bacillus is only one of the many carcinogenic agents such as tar, X rays, Fibiger's spiroptera, which, though very diverse in their nature, induce by their continued action the condition of malignancy. The period of induction with these various agencies is very long and this seems to hold good also for the true neoplasms arising in the inoculated mice, although the data are not always clearly given.

The results of this careful and laborious investigation require confirmation, for the validity of Dr. Cherry's contention depends on his pathological diagnosis of the truly malignant nature of the tumours which developed in his experimental animals. On this point we feel that he has weakened rather than strengthened his case by including conditions of doubtful malignancy.

GALLOP RHYTHM.

The *bruit de galop* and the corresponding phenomena which can be recognised on palpation have long been regarded by clinicians as signs of ill-omen, and the theories which have been put forward about the mechanism of their production are many and varied. These signs are most often found in cases of chronic nephritis with high blood pressure, and their appearance is generally taken to signify that the heart is failing. Two types of gallop rhythm have been described, the distinction between them depending on whether the additional sound occurs early or late in diastole. In the one case the second, and in the other the first heart sound appears to be reduplicated. Most writers who have attempted to probe the mystery of this peculiar sign have taken as their guide a tracing of the cardiac impulse; but owing to its variability the cardiogram has proved little better than a broken reed to those who have leant upon it. A safer clue has been followed up by H. Mond and E. T. Oppenheimer,[1] who have made a series of synchronous records of the heart sounds and electrocardiograms. Their records show that the supernumerary heart sound of gallop rhythm always corresponds in time to auricular systole, and they point out that it disappears when the auricles fibrillate. Its position in the cardiac cycle may be early, mid, or late diastole. When the heart is beating rapidly diastole is short and the contraction of the auricle, with its accompanying gallop sound, follows close on the heels of ventricular systole. During bradycardia, on the other hand, there is a long silent interval between the second heart sound which marks the end of ventricular systole and the succeeding auricular cycle. Under these circumstances the gallop is presystolic in time. And, lastly, when bradycardia is associated with delayed conduction, auricular systole and the third heart sound may occur in mid-diastole. Mond and Oppenheimer believe that the lax walls of the empty ventricle normally damp out the sounds produced by auricular systole, but that in the failing heart, when the diastolic tension of the ventricular wall is increased, the acoustic conditions are completely changed. The ventricle then behaves as a resonator and amplifies the sounds produced by the contracting auricle. This hypothesis is certainly attractive. It affords an explanation of the association between gallop rhythm and congestive heart failure in cases of high blood pressure, and harmonises with the other known facts.

PATHOLOGY OF PYORRHŒA ALVEOLARIS.

An addition of considerable value has been made to our knowledge of the morbid anatomy of pyorrhœa alveolaris by the work of Mr. Warwick James and Mr. A. Counsell [2] carried out in the Bland-Sutton Institute of Pathology at the Middlesex Hospital. The earliest changes occur in the subgingival epithelium of the gum, just below its junction with the periodontal membrane of the tooth which thickens and sends out finger-like processes into the corium. As the condition advances the epithelium grows downwards along the cement of the root and becomes attached to the latter by means of a layer of keratinised material. This is in accordance with the findings of other observers, notably H. Box and B. Gottlieb. Associated with these proliferative changes there is desquamation of the superficial epithelium in the direction of the root, forming a pocket which tends to deepen and widen. The downgrowth of epithelium along the root of the tooth is, however, in advance of the destruction, so that ulceration does not occur. So far from the pocket being lined with granulation tissue, as has been frequently stated, it is always covered by epithelium which being of new formation differs from that normally lining the gingival trough. As may be seen in carefully prepared sections, tartar is deposited upon the keratinised epithelium adherent to the cement and fills the pocket. It would appear that the lesions usually commence between the teeth and thence extend laterally. The circular ligament, which is the name given to the junction of the gum corium with the periodontal membrane, is destroyed but is reformed at a lower level concurrently with the extension of the lesions in the epithelium; its fibres, however, are less regularly arranged than in the normal state. In advanced cases the fibrous tissue may be replaced by a cellular infiltration of the plasma type and much of the support of the tooth is lost. Definite changes appear in the blood-vessels, the walls of the arteries being thickened and the veins dilated. The cytological changes are instructive. In the early stages of the disease there is an infiltration of lymphocytes into the subgingival epithelium which remains localised. In later stages plasma cells are present round the vessels; thence they extend in diffuse masses along the perivascular channels into the medullary cavities of the bone leading to the destruction of the latter tissue. In this way there is a direct path of infection from the gum margin to the interior of the bone—a point of some importance in its bearing on the problem of focal infection. There has been a tendency to assume that the open sepsis of pyorrhœa which discharges its toxins into the mouth is relatively less serious than the closed type of apical infection in which the only escape of toxins is into the blood stream. It is doubtful if this distinction holds good, for while some of the toxins in pyorrhœa may pass into the mouth and be swallowed, yet there appears to be an abundant opportunity for infected matter to be absorbed into the blood stream by means of the vessels in the alveolar bone. Polymorphonuclear leucocytes are relatively uncommon; when present they would seem to be due to a pyogenic infection superimposed on the original lesion. In spite of the implication of the word pyorrhœa the presence of pus is uncommon.

[2] Histological Investigation into "So-called Pyorrhœa Alveolaris," Brit. Dent. Jour., 1927, xlviii., 1237; The Primary Lesion in So-called Pyorrhœa, Ibid., 1928, xlix.

While it has usually been thought that the lesions in the periodontal membrane were of great importance, James and Counsell find that this structure is the last to be involved. They describe histological changes in the membrane which resemble those described by Box under the name of "rarefying pericementitis fibrosa." The bony changes consist of a progressive marginal absorption of the lacunar variety. Loss by halisteresis as described by N. Znamensky was not observed. Where the loss of bone has opened up the medullary cavities the bone-marrow undergoes changes and in due course becomes replaced by fine fibrillar connective tissue and plasma cells. The chief points of interest which emerge from these investigations are that pyorrhœa is essentially a gingivitis in its early stage, which is characterised by epithelial proliferation along the root, leading to the formation of a pocket which is always lined with epithelium. There is a progressive destruction of bone accompanied by fibrotic changes in the gum corium. The periodontal membrane is the last tissue to be attacked so that the disease is incorrectly termed a general periodontitis. The presence of pus is uncommon and when it exists is due to a secondary pyogenic infection. An infiltration with plasma cells is a constant feature and plays an important part in the spread of the disease. The various changes described are illustrated by a remarkable series of microphotographs and add much to the value of the papers.

OCCUPATIONAL SILICOSIS.

SILICOSIS is now receiving more attention than any other occupational disease, its prevalence having been grasped almost suddenly. Allied with tuberculosis it forms the most fatal and most preventable group of phthisis cases, and its occupational origin is being recognised in the granting of compensation to the victims. During the last 12 months the provisions of the Compensation Act in this respect have been extended to the grinding of metals, to the potteries, to tin-mining, to various other industries in which there is a silica dust risk, and now since April 1st to the sandstone industry. Without doubt through claims arising and medical supervision of those employed, more accurate and valuable information on the incidence of the disease will become available. Similar action is being taken in the Dominions—on the Rand, in Ontario, in New South Wales, and in Western Australia. European continental countries have so far held back, but the subject has had the premier place this week at Lyons in the International Congress on Occupational Diseases. The United States, too, are fully alive to the new knowledge; and a valuable report of a special committee has just been issued[1] on the silica hazard of men employed in building and tunnelling the Manhatton schist upon which New York is built. Over 200 men taken from work were carefully examined, with X rays and otherwise, and 57 per cent. of them showed signs of silicosis, 15 per cent. being in a fairly advanced stage. This certainly seems to justify the conclusion that silicosis is a serious hazard to rock drillers, blasters, and excavators in New York City. Study of the dust showed that both in silica content and in number and size of particles it was dangerous to health; the free silica content was from 1 per cent. to 84 per cent., and sampling showed the amount in the air generated by the pneumatic drills to be of the same order as is found in metalliferous mining. The committee have good ground for recommending that compensation should be granted by law for disability due to silicosis. Such an economic liability is bound to incite preventive measures. Simultaneously there reach us from New South Wales two Government studies, one into dust sampling in sandstone industries,[2] the other into pneumonokonioses produced by diverse mineral dusts.[3] Building on and with, and tunnelling through, sandstone at Sydney presents a problem similar to that of New York. The stone is composed of 86 to 95 per cent. quartz grains, and, when worked with machine drills, gives off a plentiful supply of fine injurious dust. The dust studies, in which the Owens's jet dust counter and the Greenburg-Smith impinger were used, are of great interest. They indicate that if each dust particle initiates a fibrotic condition, the 1-micron particle is the most dangerous, because it is in majority; if fibrosis depends on solubility of dust particles in the lungs, the 2-micron is the most pernicious, as it exposes the greatest percentage of surface; whilst, if quantity is the most important factor, the 3-micron is most pernicious, as it is heaviest. If number, surface, and weight are all factors, then sizes 1–3 are the worst. Of not less interest is the study in which from exposure to dust of orthobase basalt, of certain coals, of oxide of iron, of asbestos, and of cement, evidence is adduced to prove the production of a fine type of pulmonary fibrosis, as distinct from silicosis. People with this type of fibrosis do not seem to be especially liable to tuberculosis, although other pulmonary diseases concern them. A whole new group of pulmonary fibroses is here under observation.

BLOOD PRESSURE AND DISEASE.

ALMOST every medical discussion nowadays shows the reversion of medical thought towards diatheses and types of constitution. The one on blood pressure at the Hunterian Society on March 25th proved no exception. Dr. Halls Dally, the opener, while enunciating his belief that the problem could only be rationalised from the biological standpoint, nevertheless ventured to lay down a certain standard of blood pressure in relation to age. Physiologically, he said, the physician might expect to find a blood pressure of 80/50 in a child of 5, of 100/50 in a child of 10, and a sharp rise with the onset of gonadal function at puberty to 120/75, while between the ages of 17 and 40 a man might be expected to show a reading of 125/80, and a woman of 115/75, both sexes rising slowly up to 135/88 at the age of 60. For venturing to give even this rough guide, however, Dr. Halls Dally was severely criticised by subsequent speakers. Dr. Campbell McClure declared that he had no interest whatever in an "average" blood pressure. Dr. Temple Gray averred that no statement had done more harm in medicine than the dictum, "A man is as old as his arteries." Some men would live to a ripe old age with arteries in an apparently hopeless condition; others would die young with apparently healthy vessels. He had seen men very ill with nephritis with a blood pressure of 85, and had known a man walking about with a blood pressure of 300. Dr. Temple Gray also pointed out that Kretschmer's four psycho-physiological types showed distinct differences in their blood-pressure levels, and Dr. McClure drew a vivid picture of the two constitutions, the high and low blood-pressure types. The person of the low-pressure type was an unsatisfactory child at school. He might have artistic talent, but he could not shine at intellectual work. He suffered from lassitude, headaches, insomnia, and evening fatigue. He was seen by the doctor in early manhood, but seldom when he was over 50. Slow to develop, he was rarely able to put his abilities on the market before he was 40, but by the time he was 60 he had far outdistanced his high blood-pressure rival, who had shot ahead at school with exuberant vitality, carried off all the prizes in his early professional career, and died intellectually at 38. The high-pressure type came to the doctor much later in life, and suffered from many disorders of cardiac and renal function to which the low-pressure man was a stranger. The latter has, Dr. McClure thought, to beware chiefly of early cancer, which is apt to hit him before he has time to react to the environment of ageing. There is a certain structural difference between the two types which is revealed in the shape of the heart. The low blood pressure type has a tubular heart, is always short of calcium, and is liable to tuberculosis; the high blood pressure type has the "bullock-heart," is always full of calcium, and has difficulty in elimination. If he contracts tuberculosis, he recovers. Dr. Halls Dally pointed out the peculiar resemblance between the symptoms of high and low blood pressure, and described them as expressions of two opposite forms of failure to adapt to the environment. Nevertheless, there must always remain a certain number of patients in whom abnormal blood pressure, as a direct measure of the load the heart and valves have to bear, and of the vasomotor tone, calls for therapeutic measures. The decision to treat should never be based on simple systolic readings alone. The diastolic, the differential, and probably in future the arteriolar and capillary pressures, will all prove of great significance.

WE regret to announce the death on April 1st, at Hove, of Dr. Robert Lauder Mackenzie Wallis, lecturer in chemical pathology at the University of London, and formerly chemical pathologist at St. Bartholomew's Hospital. He was in his forty-fourth year.

Modern Technique in Treatment.

A Series of Special Articles, contributed by invitation, on the Treatment of Medical and Surgical Conditions.

CCXCI.—THE TREATMENT OF VULVAR AND ANAL ECZEMA.

PART II.*

X Ray Treatment.

IN the past it has often been claimed that X rays are the best treatment for these cases of pruritus and eczema of the ano-genital region. X ray treatment used to be my chief therapeutic agent, but now I regard it as no more than an aid. I would thus summarise my conclusions:—

1. When treating a severe, chronic case one correct dose of X ray is of great value, often causing a marked step forward in the progress whilst other treatment is continued.

2. After trial of many doses, I have found that the method which has given most satisfactory results is one dose, given thus: H.2 unfiltered, and H.2 or H.3 filtered through ½ mm. aluminium. The pastille is placed on the skin. I use the Hampson tintometer and Sabouraud pastilles obtained from Paris.

3. X rays do not alone bring about a cure.

4. X rays are probably unnecessary for mild non-œdematous cases; these often respond to simpler measures.

5. One full pastille dose of X ray, even if filtered through ½ mm. aluminium, can be followed by telangiectases. With the milder tubes of pre-war years these did not appear for several years. Nowadays, with the higher voltages employed, the same dose is soon followed by pigmentation and often by telangiectases within a year.

6. When relapse has occurred, even if long after several small doses of X rays had been given at intervals, the administration of one suitable dose does not cause the usual benefit. This resistance to repeated X ray dosage has been noted by many observers in the case of rodent ulcer and other dermatoses.

The following case shows how little X rays alone can do for a severe form of this malady:—

Mrs. P., aged 34, in June, 1919, had tried many remedies and had been under the care of two dermatologists for fissured and œdematous eczema of the vulva and anus. She had become a tearful wreck from lack of sleep. She was given the usual calamine with carbolic lotions, and mercurial and cocaine ointments. Just under one pastille dose of X ray was administered by the method above described. As the nervous system was so undermined she could not be expected to refrain from scratching, and hence it was impossible to treat her whilst at work. She was put to bed; all the diseased region was painted with pure carbolic acid. This was followed by fomentations with 1 in 40 carbolic, changed every two or three hours. The parts were kept thus so raw and sore that she could not scratch, and the habit was broken whilst sleep was obtained. When the outer layer of mucous membrane and skin had healed she had carron oil, calamine cream, and daily high-frequency treatment to both vulva and anus. Then the vaginal discharge was dealt with. When she was seen after the August holiday she was almost well. In September a 2/3 divided X ray dose was given. She became completely cured and had remained without the slightest relapse when I heard from her in 1926.

High Frequency.

Again one must take into account the difference of modern instruments and those of former days. Low tension diathermy is used to-day. In pre-war days the vacuum tubes were attached to the Oudin resonator of the high voltage high-frequency machine. The tubes of the older machine convey an entirely different sensation to the patient; they are less warm, but more stinging; moreover, especially when combined with the condenser couch, they aid the general health of the patient. When I speak of high-frequency vacuum electrodes I mean the tonic dose obtained from a Dean instrument with noisy spark gap in glass container, manufactured in 1906. From time to time all wiring has been replaced, and the Leyden jars have given place to condenser plates in oil. No diathermy tube which I have tried conveys anything like the brilliant invigorating sensation of the older instrument. Treatment by the vacuum tube is especially indicated when there is much swelling; this is appreciably reduced during the sitting of 15 to 20 minutes. I use a tube specially made, large enough to fit over the entire vulva. This is pressed upon the part and held in close contact; it is applied daily for 6 to 12 days. Many a patient whose suffering was so great that no local application alleviated the irritation enough to prevent uncontrollable night scratching has remarked that improvement dated from the first application of the high-frequency tube. The general tonic effect is also most helpful in neurasthenic and toxæmic cases.

---

* Part I. appeared last week.

Miss A., aged 59, seen in 1925 with extensive eczema of the vulva and anus. There was a slight vaginal discharge. She had suffered for 15 years and tried many remedies. She made great improvement within a week after one X ray and light twice a week, and the usual mercurial ointment and protective care. But she spontaneously remarked that the first great relief from irritation followed the first high-frequency application. She was practically cured within five weeks and remained so when I last heard in 1927.

Ionisation.

In some cases I have given zinc ionisation. Fissures are cured by 1 or 2 m.a. for 4–8 minutes. When ionisation is given over a larger area it has the drawback that the initial increase of irritation causes patients to lose confidence. The value of ionisation to the cervix with zinc or copper has at long last been recognised as a most beneficial method of treatment of discharge. A relapse of pruritus and eczema is often found to be due to a renewed discharge.

Miss N., aged 44, seen in May, 1913, had had severe vulvar eczema for six years. She was put to bed and the parts painted with pure carbolic acid. In these days I had not realised the causal importance of a slight vaginal discharge. For the time she was cured but relapsed in July and again in September. Then at last I treated the discharge, giving copper and zinc ionisation to the cervix. She became cured and remained so when I last heard from her in 1926, when she came to see me.

Ultra-violet Light.

Of recent years this method of treatment has received enthusiastic supporters. Details of the types of case treated are singularly lacking in most of the published reports. What other form of treatment is employed—ointments, lotions, powders, protective or general hygiene—is scarcely if ever mentioned by those who acclaim the value of ultraviolet light as a panacea for this distressing malady. I tried the tungsten arc and the mercury-vapour lamp, and have formed the opinion that ultra-violet light is certainly a useful adjunct to other treatment; I have never relied upon it alone. It seems more beneficial in treatment of the vulva than of the anus, but it has not been in use long enough to compare its value with other methods. Many patients have remarked that the tungsten arc was more beneficial than the mercury-vapour lamp. I became convinced of the value of true sunlight by its effect on two women who could not stay in London long enough to have more than a few days' preliminary treatment. Both had profuse muco-purulent discharge from the womb, so irritating that the entrance of the vagina, as well as the labiæ, was swollen and tender. The usual X ray dose was given, ionisation to the cervix, and careful directions as to douching and guarding the infected areas from the discharge. The patients went, one to the Riviera, one to the South of England. They exposed the parts to the direct rays of the cool morning sun for half to one hour respectively. Both became cured and both attributed high value to the sunshine.

A word of caution must here be given concerning the application of X ray and ultra-violet light on the same day. If as much as 4/5 of a pastille, even if filtered for half time, is followed by tungsten arc, concentrated, 1 minute at 12 inches, acute erythema and swelling follow. This is intensely irritating and painful for over a week and alarms the patient. On the other hand, it brings about a rapid cure. I learned the danger of X ray and ultra-violet at the same sitting by my experience with four cases. I had treated an extensive eczema in a diabetic patient by this method, hoping to hasten matters before I left for a holiday. Later, she told me she had suffered greatly, but the subsequent cure had been miraculous in its rapidity and completeness. Three other severe cases reported similarly. Two were so grateful that they did not mind the early reaction; the other, however, never forgave the suffering; so I have not dared to repeat this method.

Local Applications.

The recommended creams, ointments, and lotions are legion. For times of urgency, when irritation is unbearable, menthol (grs. iv.—℥i.) relieves, but gives rise to much pain when cracks are present. Cocaine 2 per cent., or butyn 5 per cent., in lotion or cream, are very useful; so also are 1 or 2 per cent. solutions of creolin or carbolic acid. Some find a saturated solution of boric acid the best application. It comforts the patient to be warned of the fact that different applications suit at different stages of the disease, even at different times of the day; so changes must be rung. When the patient can go to bed and have the advantage of skilled nursing, many now rely upon coal-tar. When there is thickened leathery induration and the patient can lie up, painting with pure carbolic acid, followed by compresses of 1 in 40 carbolic, soon causes exfoliation. Diathermy sparking brings about the same effect. The mucous membrane is then protected by some soothing cream, or carron oil will answer when the mildest powder in a cream causes discomfort. Many patients cannot lie up for longer than a few days. The mercurial preparations answer in most cases: hyd. ox. flav. gr. i. to ℥i. of paraff. moll., calomel grs. xx., zinc oxide ʒi., paraff. moll. ℥i. Lassar's paste, or a calamine cream with 1 per cent. carbolic acid, suits others better. When the parts are no longer swollen and cracked, a dry dusting powder, equal parts of talc, bismuth oxychloride, and zinc oxide, with a little boric acid, is an excellent application for use by day.

Before 1910 very little was done for these cases except the application of cocaine ointment 2 per cent., and painting weekly with silver nitrate grs. xvi. in spt. etheris nitrosi ℥i. As a result of ignorance of the origin of the eruption, no care used to be taken to remove sources of infection of the skin and mucous membrane. The urine, we used to be taught, was a bland fluid which could not irritate the skin. Again, all women were supposed to have, from time to time, more or less vaginal discharge; hence one of the chief sources of infection of the vulva was not dealt with. Patients used to be told, even by dermatologists, that the condition was incurable, or "a neurosis"; and only palliative treatment was given, consisting for the most part of cocaine, silver nitrate, mild tar, or mercurial ointments and bathing with boric lotion. All of these are valuable, and are still used to-day.

A Few Failures.

It is always instructive to consider one's failures. Before the war, undoubtedly many relapses of my cases of vulvar eczema were caused by unrecognised slight vaginal discharge. Many of the relapses of pruritus and eczema ani, as I have already said, were due, I at last realised, to paraffin leakage. Again and again, when such patients came to me with a relapse, I would find tinges of fæcal matter between the anal ridges. Other unrecognised causes of relapse were possibly due to the fungus described by Castellani.

Notes of two cases of comparative failure are given below:—

Miss J., aged 47, who said she had had eczema on and off all her life, was first seen in May, 1917, with severe eczema of anus and vulva. She was a delicate woman of the thin, sallow, nervous type. She had had six X ray weekly doses from a physician skilled in X ray treatment, but had not received the slightest benefit. Her case provided another proof that X ray is only an adjunct to the correct management of these cases, and cannot alone cure the condition. At that time I relied on a mild antiseptic ointment, and the dosage of X ray I had found to be most efficacious. The result was successful at first, in spite of the fact that previous X ray dosage told against a good prognosis. But she relapsed in 1919; and again in 1922, though not severely. She was only able to stay in London a day or two at a time, and so no continuous observation or treatment was possible. Eventually she wrote she was greatly improved but subject to a mild degree of periodical recurrence of her old trouble. This case failed because of the obstinacy of a condition which had had too many doses of X ray and because of the defective diet and lack of exercise taken by an impoverished and unoccupied woman with few interests in life.

Miss S., aged 45, was sent to me last year with vulvar eczema dating from the age of 17. She was of poor mentality and physique, with a lengthy history of illnesses—including Graves's disease and colitis. Again and again in this case, just when success seemed assured, the parts would swell up and progress would be retarded for many weeks. At length her companion told me that although scratching was denied, in reality the sufferer often indulged in a truly alarming orgy of it. After trying everything, she was sent to hospital where the surgeon excised the parts. This failure was due to time in a home being limited, owing to financial reasons, and also to the fact that it was impossible to break off her habit of scratching.

Examples of Successful Cases.

Two difficult successful cases, illustrative of types in which the disease was due to different causes, may also be of interest.

In 1918 I saw Miss E., one of the most widespread cases I have ever seen in a young woman of 28. She had become very neurotic from lack of sleep, due to the incessant irritation and worry which had existed despite a variety of treatment and the doctors for over three years. Both vulva and anus were swollen and eczematous. There was a prolonged history of constipation, and apparently she had suffered from true colitis some years previously. No doubt the mucus which exudes in these cases had infected the skin with streptococci and started the chronic eczema. She caused me much anxiety, as in her sleepless nervous state it was exceedingly difficult to make her abstain from scratching. Indeed, the sole successful method was the application of a stinging lotion containing menthol and spirit, which caused soreness long enough to break the habit. *Sleeping draughts carried her over the early days until* the X ray and daily high-frequency applications reduced the irritation enough for her to be able to coöperate loyally in the progress towards the cure which occurred after two months. When I heard from her four years later she had had no recurrence.

Mrs. T., aged 56, first seen in March, 1926, had suffered from pruritus and eczema of vulva and anus on and off since the menopause. All the time she had had treatment of all kinds, local and general, from several most careful physicians. In autumn, 1924, she had had 6 ¼ pastille doses filtered through 1 mm. aluminium. In spring, 1925, she had had 10 almost weekly doses of X ray 1/3 and ¼ pastille, three not filtered, the others filtered through ½ and 1 mm. aluminium. The patient was athyroidic, with blue upper arms and breasts, and much abdominal distension. When she was sent to me, she had a severe recurrence of eczema, extending to anus and intergluteal fold. The only causal history I could obtain was that two years previously she had noted intense irritation coincided with vaginal discharge. This led me to decide to treat the uterine discharge. A course of ionisation treatment to the cervix was begun. At the same time, as the vaginal discharge seemed insufficient to cause such widespread eczema, a catheter specimen was taken and revealed numerous coli and streptococci, from which an autogenous vaccine was prepared and given. Less than my usual dose of X rays was given to the vulva, anus, and intergluteal fold. The mercury-vapour ultra-violet light was given twice, then thrice a week, to the whole region; 2 feet distance for two, then three minutes—eight doses in all. High frequency, nine doses of 15 minutes were given to the vulva daily. Thyroid, pituitary, and a diet were ordered. Every soothing cream I could prescribe, as well as the usual protective ointment for the vulva, and coal-tar for the anus, was tried; of all these the patient preferred lipol. As she was seen daily, changes in treatment were made according to the daily indications. Within a month all the affected parts looked normal. The vaccine was carried on after she left London. When she ceased vaccine in September, pruritus began, and on resumption of vaccine it ceased. I therefore advised her to carry on with vaccine for a year. The local trouble remained cured and a much higher level of general health was maintained. She attributed the lasting results to the vaccine. I attributed much of the success to the improvement of the general health with thyroid and corrected diet.

Principles Guiding Local Treatment.

When called upon to treat a case of vulvar eczema the practitioner should pass in review all the causes, and remember that more than one may be in operation. The principles guiding the local treatment are those employed for all skin diseases. Soothing remedies are indicated where there is hyperæmia and acute inflammation, stimulating remedies when the condition has become chronic, exfoliating applications in late stages of induration. When only hyperæmia is seen, as in the early stage of a colon bacillus infection arising from external sources, it is surprising how often it will yield to simple boric ointment. In all acute conditions, calamine lotion or cream is a justly popular soothing remedy. It is important to use only the best powders; I have often found a calamine lotion contain so much gritty material that it was not a soothing, but a very irritating application. When *the inflamed parts show moist exudation*, Lassar's paste (zinci oxidi, amyli, āā ʒi.–ʒii., paraff. moll. ℥i.), without salicylic acid, answers well; when there is dry induration of long standing, the mild mercurial or tar ointments do best. Pure carbolic acid, strong salicylic acid, or diathermy sparking will cause exfoliation; soothing remedies are then applied to the fresh membrane beneath. X ray treatment is indicated only in chronic conditions, especially if the patient can be seen but seldom. The full effect of the dose is not gauged until about ten days have elapsed; the patient should be warned of this fact. When the patient can be seen frequently other methods should be tried before resort to X rays. High frequency is especially indicated when there is much swelling, in both acute and chronic cases. The small portable apparatus is not without value when the large instrument is not available. The correct technique for the best use of ultra-violet light is not yet known. A strong dose is excellent; but the patient should be told that this involves pain and staying in bed. The slower methods hasten cure, especially when pigmentation occurs. Direct sunlight in our climate is rarely too strong, and still more rarely is it available for many days in succession; the practitioner need not fear to order exposures of half to one hour daily for one or two weeks.

General treatment is of the utmost importance when the urine contains sugar or micro-organisms. It can often be foretold, from the aspect of a patient, that a catheter specimen will reveal the presence of colon bacilli, streptococci, or both. In young women the pulse is rapid, the heart often dilated; in older women there is frequently evidence of defective thyroid and pituitary action. Colon bacillus infections are prone to relapse, largely because the patients will not persevere with the local protective measures necessary to prevent reinfection. When colon bacilli and streptococci are found in the urine vaccines play a prominent part in treatment. With sensitive, delicate women, who have a rapid pulse, it is important to avoid reactions. Overdosage prolongs their illness; hence the initial doses must be small, say 50,000, with cautious increase up to 1,000,000. Both streptococcal and colon bacillus vaccines are helpful in extensive eczema starting from the anus, for they aid the general resistance of the patient, and no measure which achieves this can be omitted. At the menopause, and at any time when there is evidence of deficient endocrine activity, the correcting gland should be administered. In the near future the biochemist will explain to us why calcium lactate is so often useful in these cases.

Special Articles.

THE ALLEGED TOXIC ACTION OF ACCESSORY FOOD FACTORS.

BY J. CLIFFORD HOYLE, M.B., B.S.,
ERNEST HART MEMORIAL SCHOLAR.

(From the Pharmacological Laboratory, Cambridge.)

VITAMINS, or accessory food substances, in relatively minute amounts are essential constituents of the perfect food. As it is now customary to administer these substances in quantities out of all proportion to those found in natural foods, it is of some importance to inquire how far, if at all, these excessive amounts are objectionable.

Hopkins[1] in 1923 first suggested that a balance of vitamins in the diet might be an important factor in the maintenance of normal health. He found that rats failed to grow when an excess of cod-liver oil was given in addition to the normal diet, but that this event could be prevented by administering an excess of vitamin B, as marmite. Evidence was not available at that time to show whether vitamin A, vitamin D, or some other constituent of cod-liver oil was the factor responsible for the disturbance of health. Takahashi[2] [3] had previously claimed that a purified extract of vitamin A administered to rats in excessive amount caused cessation of growth and later death; but Drummond[4] refuted this statement and showed that no harmful results followed the administration of large amounts of active preparations. Magliano[5] also found no detrimental effects to growing animals from large doses of vitamin A.

It is evident from these results that no reason at present exists to prove that excess of vitamin A was the poisonous factor in the observations made by Hopkins with cod-liver oil. Mouriquand and Michel[6] in guinea-pigs and Bezssonoff in clinical cases[7] found that large doses of cod-liver oil were detrimental in scurvy. Euler and Widell[8] claimed that an excess of cod-liver oil gave rise to faulty growth and bone formation in rats, but that this was prevented by increasing the allowance of vitamin C. Arvay[9] and Agduhr[10] have recently reported degenerative changes in the myocardium of rats fed with excess cod-liver oil, but Höjer[11] criticised the latter's results on the ground that an inadequate amount of vitamin B complex had been given. Hartwell[12] and Sure[13] found that an excess of cod-liver oil given in addition to a normal diet resulted in failure of growth and gestation in female rats. This has been confirmed by Harris and Moore,[14] who have shown that if the allowance of vitamin B complex, given as marmite extract, is increased from about 6 to 12 per cent. growth proceeds fairly normally but gestation is still rare, and when it occurs usually terminates abnormally. They found also that when an excess of the unsaponifiable material of cod-liver oil was given with a diet in which vitamin B complex was absent the rats lost weight more rapidly and suffered from skin lesions simulating those of pellagra.

Interpretation of Experimental Observations.

It is obvious that the interpretation of such experiments is at present a matter for conjecture; they are often regarded as examples of defective vitamin balance though without valid evidence. In no case has it been possible to administer a reasonably pure preparation of the vitamins tested, and until this can be done it must remain questionable whether the changes established are not the result of some toxic factor other than that of deficient vitamin balance. The position at present is that although considerable evidence exists to show that an excess of cod-liver oil is definitely harmful in animal experiments, and some to suggest that when increased marmite is given at the same time the effects may be modified, we have no reason to suppose that such changes are due to the vitamin content of the oil.

Since the discovery by Rosenheim and Webster[15] that irradiated ergosterol is the parent substance of vitamin D, it has been possible to administer this vitamin in far larger doses and in a purer form than has been the case up to now for any other accessory food factor; and already many observations have been recorded showing the effects of large doses in animals taking otherwise normal diets. Pfannenstiel[16] found that grossly excessive amounts resulted in the death of young rabbits. Kreitmair and Moll[17] extended this work and found that mice, rats, cats, rabbits, dogs, and guinea-pigs were killed in periods ranging from 15 to 40 days with doses varying from 1 to 40 milligrammes daily. In all cases the animals lost weight profoundly, and at post-mortem examination the spleens were atrophic and the small intestines showed hæmorrhagic enteritis. But the most striking lesions were found in the vascular system, in which an extensive arteriosclerosis, involving the aorta and other main arteries, was present. In most of these lesions considerable deposition of calcium salts occurred, and this was a feature also in the lungs, kidneys, and intercostal muscles. In most cases this was accompanied by a secondary sclerosis. Kreitmair and Hintzelmann[18] have since confirmed this, and described in detail the pathological changes found; and Harris and Moore[14] have noted that death may occur in rats though they describe no post-mortem changes.

There is thus a considerable body of evidence to show that irradiated ergosterol when administered to animals in large amounts possesses highly toxic properties. The German workers considered that these changes constituted a "hypervitaminosis." Dixon and Hoyle[19] failed to confirm these results; when a few mg. were given daily to rats no changes were found. On the other hand, when the irradiated ergosterol varied from 11 to 18 mg. daily in a diet otherwise normal the animals failed to grow, and at post-mortem examination urinary calculi were found; but lethal effects and the changes described by the German workers were consistently absent. Klein has also failed to confirm the lethal effects in a recent investigation.[20]

The Method of Irradiation of Ergosterol.

In view of these contradictory results with preparations of irradiated ergosterol of similar antirachitic potency, Dixon and Hoyle suggested that another factor might be at work producing direct toxic action. They emphasised that the method of irradiation might well be a crucial factor in this connexion. The ergosterol used in their experiments was irradiated in solution in oil and in the absence of oxygen. The German workers did not state their method of irradiation, but in the experiments of Harris and Moore, in which corresponding lethal effects were found, the irradiation was carried out in alcoholic solution. It may well be that when irradiated in this way ergosterol forms some toxic by-product in addition to vitamin D, whereas when the irradiation is effected in an oily medium, as occurs in nature in the epidermis, this does not occur.

The position on this question is at present, therefore, open, though it is obvious that it is important. If the suggestion made by Dixon and Hoyle is substantiated then ergosterol for commercial use must be irradiated in oily solution. In this country this already obtains, but abroad an alcoholic or ethereal solution is largely employed. It is true that the toxic doses in animal experiments are exceedingly high compared with the therapeutic doses, but it should be remembered that these experiments have been made only on normal animals, and it is not known how far this ratio applies in initial vitamin deficiencies or other nutritional disturbances.

Calcium Deposition.

If the position of the German workers is confirmed and their results are in fact a true "hypervitaminosis" then a considerable addition to our knowledge of the ætiology of experimental arteriosclerosis will have been made. For it is generally believed at present that two stages occur in the production of this condition—an initial injury, mechanical or toxic, to some part of the vessel wall, and later compensatory proliferative changes and sclerosis, with calcification of the dead tissue at the same time. If this conception is upheld either vitamin D must be sufficiently toxic in large doses to injure the vessel wall directly, or it must be assumed that the injury is brought about by primary calcium deposition in the vessel wall, the result of an excessive mobilisation by the vitamin. If the former hypothesis were true it would constitute the first known instance of a physiological substance producing an effect in excessive amounts that is unrelated to its normal action; if the second hypothesis were true, then it is evident that arterial lesions, due to primary calcium deposition in the vessel walls, would be expected in all conditions associated with excessive calcium mobilisation.

In clinical arteriosclerosis there is no evidence to suggest that excessive calcium mobilisation is a factor in the production of the injury to the vessel wall; the blood calcium has only been recorded in essential hypertension but here it is normal.[21] and in the earliest lesions calcium deposition is not found. Calcium deposition is essentially a secondary phenomenon. On the other hand, it is known that widespread "metastatic" calcification occurs in conditions where a pronounced degree of bone resorption is taking place, such as in osteosarcoma, osteomalacia,[22] and osteitis fibrosa.[23] In these diseases the blood calcium is usually higher than normal [24-26]; and in many, if not all, cases of osteomalacia and osteitis fibrosa parathyroid tumours or hyperplasia occur.[27-33 etc.] Recent work [34-36] has shown that the parathyroid hormone raises the blood calcium by mobilising calcium from the soft tissues and ultimately the bones. This strongly suggests that in the diseases mentioned the bone resorption and raised blood calcium level are due directly to increased functional activity of the parathyroid glands. In such cases there is no evidence of any preceding injury to the tissues and the metastatic calcification may depend entirely upon the increase in blood calcium. This view of the part played by the parathyroid glands in these conditions is supported by the work of Hueper,[37] who found extensive calcification in the organs of dogs that had received repeated injections of Collip's parathyroid hormone.

All this evidence suggests that under certain conditions calcium deposition in tissues may occur readily without gross preliminary injury. Histological evidence, however, in no case excludes the possibility of some damage to the cells which is not revealed by microscopic techniques. Nevertheless, it may be that the calcification found by the German workers to occur in animals that have been receiving a marked excess of vitamin D is similar to that found in such conditions as osteomalacia and osteitis fibrosa in that it is independent of preliminary gross injury to the tissues. If this is the explanation such animals should show a pronounced hypercalcæmia. Klein [20] found a 50 per cent. increase in the blood calcium in his experimental rats, but as he did not state in what solvent his ergosterol had been irradiated, and did not report post-mortem findings, his figures lose their main value. Apart from this no investigations into the point have yet been reported.

Although Dixon and Hoyle [19] failed to confirm the results obtained by the German workers, they found calculi composed of calcium phosphate in the urinary tract, with secondary mechanical changes in many cases. This has been confirmed in unpublished experiments by the writer. Dixon and Hoyle pointed out the possible importance of these observations in the ætiology of urolithiasis in tropical countries, where calcium phosphate calculi are common, apart from bilharzia infection. They suggested that prolonged exposure to the very powerful solar rays of such climates might well produce excess of vitamin D in the skin; and this appears probable when it is considered that only about 2 per cent. of those rays which have maximum ability to produce vitamin D from ergosterol penetrate the pigment layer. Therefore, under normal conditions, irradiation of the skin ergosterol must occur in that part which is superficial to or included in the pigment layer, and this must apply also under conditions of excessive irradiation.

Vitamin A Deficiency.

The same authors further suggested that in the case of natives in tropical countries a second factor which is well established for some populations—lack of vitamin A [39]—might play an important part. It is known that deficiency of vitamin A predisposes to infective processes,[41-49] and that the urinary tract is frequently affected. Moreover, it has been shown [47 and 50-55] that with such a deficiency in the diet the formation of calcium phosphate calculi in the urinary tract is frequent and it is probable that the two conditions, infection and urolithiasis, are related as cause and effect.

In the case of populations habitually consuming diets defective in vitamin A and at the same time exposed to the possibility of forming excessive quantities of vitamin D from solar irradiation, it is obvious that the two factors would work in the same direction to produce urinary calculi. In this way a degree of deficiency of vitamin A or excess of vitamin D either of which acting separately might be quite inadequate to induce calculi formation, when acting together might well do so. Such a condition would illustrate clearly the significance of "vitamin balance" in the case of the fat-soluble accessory factors.

MEDICINE AND THE LAW.

Acquittal on Charge of Criminal Abortion.

Dr. Daniel Evans Powell, of High-street, Tooting, was acquitted at the Central Criminal Court on March 27th on an indictment charging him with the manslaughter of Mrs. Doris Ruth Simmons, a London schoolmistress, and with using an instrument or other unknown means to procure her miscarriage. Dr. Powell, who pleaded "Not Guilty," was defended by Sir Patrick Hastings, K.C. The husband of the dead woman gave evidence that on Nov. 25th he went to Dr. Powell's surgery and told him that some capsules which the doctor had given his wife did not agree with her, and asked if he would give her something else. Dr. Powell, he said, gave him two bottles of medicine and a packet of lint. Next day Dr. Powell gave a certificate that Mrs. Simmons was suffering from influenza and rheumatism. After further visits from Dr. Powell, Dr. Le Maistre (the usual family doctor) was called in. On Dec. 10th, Dr. Powell gave another certificate that Mrs. Simmons was suffering from gastric enteritis. Sir Bernard Spilsbury, who made a post-mortem examination of the body on Dec. 14th, attributed the death to syncope as a result of abortion, septic condition, and inflammation of the kidneys. He stated in evidence that the abortion had, he considered, been brought about by the passage of an instrument, and that it must have been done by a skilled person. Dr. F. J. McCann, of Upper Wimpole-street, giving evidence for the defence, said that a woman suffering from nephritis might have a miscarriage in the early stages of pregnancy. The evidence of the deceased's symptoms, he said, disclosed a common condition, and there was nothing in the symptoms to indicate that miscarriage was other than natural. Dr. Powell in the witness-box denied having performed any operation. A half-hearted suggestion by the prosecution that he had administered morphia to the dying woman to prevent her making any admission or confession was also repudiated. It was complained by the defence that Dr. Powell had not had a proper opportunity of being represented at the post-mortem examination.

Dr. Powell had been committed for trial by the magistrate at the police-court for South-West London as well as on a coroner's jury's verdict of manslaughter. Mr. Ingleby Oddie's summing up at the inquest was to the effect that Mrs. Simmons, a schoolmistress, whose youngest child was 8 years old, was anxious to have no more children; that she spoke on this subject to her husband, to a Miss Marsh, who got her some pills which proved ineffective, and to Dr. Le Maistre, her family doctor, who strongly dissuaded her from any kind of attempted abortion, whether by drugs or otherwise; and that it was in these circumstances, when the pills and the medical adviser had failed her, that she had recourse to a doctor whom she had never before consulted. The recent verdict of "Not Guilty" at the Central Criminal Court cancels, of course, the coroner's jury's verdict of "Guilty of Manslaughter" delivered several weeks ago. As was pointed out last year in connexion with the trial of Mrs. Pace, there should be some provision by which a subsequent acquittal has the effect of removing from the records any trace of a verdict of "guilty" found by a coroner's jury.

The Locking of Parked Cars.

Recent prosecutions have drawn attention to the official prohibition of the practice of leaving a motor-car at a parking place in London with locked doors. This was made an offence by the London Traffic (Parking Places) Regulations, 1928, which prescribe not only where a car may be parked, but also the conditions of parking. The material parts of the London Traffic Act, 1924 (which authorised the making of such regulations) came into operation on Oct. 1st, 1924. The Minister of Transport made his first regulations on the subject in September, 1925. These contained a scheduled list of the prescribed parking places in London, and set forth various restrictions backed by a penalty of £5. Drivers, for instance, were not to leave their engines running, nor were taxi-cabmen to ply for hire while at a parking place. For our purpose the most important clause is that which required the driver of a parked car to comply with any directions given him by a constable in uniform, including a direction to move his car from one position to another. In January, 1928, this code of regulations was superseded by a fresh one. Again there was a scheduled list and a set of restrictions; but this time it was enacted (by Article 4) that a driver must not only move his car if required, but must also "so leave the vehicle that it may be removed or moved from one position to another by manual power." No doubt by this time the mechanical devices for locking cars had become more common. As a policeman is empowered in emergency to cancel any parking privilege, and as a policeman or other authorised person may move a parked car "for any reasonable cause," it is naturally difficult to allow cars to be locked. Motorists who have escaped prosecution have sometimes found that fate has dealt hardly with tyres and mudguards. The checking of theft has to be weighed against the importance of being able to move a stationary car. The stealing of dangerous drugs and scientific instruments from medical practitioners' cars has been by no means unknown. The insurance companies have doubtless made their representations to the police, and statements in Parliament indicate that the Home Secretary and the Minister of Transport will unite in the search for some satisfactory compromise. It is hard to deny the motorist his place in a public street, but parking is officially deemed a concession. The present system is extraordinary, in that the men in charge of a parking place are not regular officials; it is understood that they are not only unpaid by the Minister or by the police, but that they have actually to purchase a licence before they can undertake their duty. They look for remuneration, therefore, to the motorists they oblige.

The motorist's grievance is that he has been left unaware of the regulations, though the Minister states that a copy of them is exhibited at each parking place. It does not seem, however, that the regulations are to be deemed an instance of bureaucratic secrecy. Under the London Traffic Act all proposals for regulations have to be sent for advice and report to the Advisory Committee on which all interests (those of the private motorist as well as those of the Home Office, the Minister, the police, and the local

authorities) are represented. In this particular instance the Minister notified in the *London Gazette* in August, 1927, his intention to make regulations; his notification stated where copies could be obtained. When he actually made them in the following January a communiqué was issued to the press, and copies were laid before both Houses of Parliament for 28 days, during which objection could have been taken to them. But he would be an optimistic official who assumed that Members of Parliament read all the papers which are laid before the House, or that motorists make a regular study of the *London Gazette* or of the files of Statutory Rules and Orders. In this particular case the making of regulations seems to be safeguarded by adequate publicity, but we have now so many laws that we are obliged to be ignorant of some of them.

The Society of Apothecaries and Mr. Roche.

An advertisement in the "Personal" columns of the *Times* of March 28th conveys the thanks of Mr. Raphael Roche to his friends who signed the petition to the Society of Apothecaries, organised by Sir George Hume; it also announces that the Society is not proceeding with its contemplated action. The reference is understood to be to proceedings threatened by the Society of Apothecaries of London under the Apothecaries Act of 1815. Mr. Roche, unregistered as a medical practitioner, and uncertificated as an apothecary, was informed by the Society that, unless he would give an undertaking never again to act as an apothecary within the meaning of the Act while lacking the statutory qualification, legal action would be taken to restrain him and to recover penalties. The matter being no longer sub judice, it is possible to discuss the material issue whether Mr. Roche has, in fact, acted as an apothecary. In a case noted in THE LANCET some months ago it appeared that Mr. Roche had treated with powders a patient who shortly afterwards died of cancer; an analyst gave evidence at the inquest that the only discoverable ingredient of the powders was cane sugar; Mr. Roche did not throw any vivid light on the nature of his prescription; he stated that his method was to use drugs in intangible quantities.

The Act of 1815 referred in preamble to the charter of James I., which (subject to modifications) it confirmed. It recited the "duty of every person using or exercising the art and mystery of an apothecary to prepare with exactness and to dispense such medicines as may be directed for the sick by any physician lawfully licensed," and it penalises those who "knowingly, wilfully and contumaciously" refuse to compound medicines, or who compound them "deliberately or negligently, falsely, unfaithfully, fraudulently or unduly." Three sections of the Act are specially material. Section 14 forbids persons to practise as apothecaries in any part of England or Wales unless they have first been examined and have received a certificate of due qualification; Section 20 backs up this prohibition with a fine of £20; and Section 21 allows no apothecary to recover charges in a court of law unless he proves that he has a certificate to practise. This restriction upon practice by unqualified apothecaries still holds good; it was upheld in litigation in 1885 and on other occasions. So far as the decided cases go, they seem to show that at first, when the 1815 Act was newly passed, an apothecary was regarded as a mere compounder of prescriptions. Later, to judge by a case in 1843, the apothecary had established himself as a person who applied himself to the cure of disease by medicine. It would have been interesting to have had a judicial decision on the issue whether Mr. Roche's treatment by powders containing cane sugar and other intangible ingredients does or does not amount to acting as an apothecary. A letter from his solicitors, quoted in a recent newspaper article, contends that the 1815 Act was designed to protect the public from quackery, and that the Act does not apply to Mr. Roche. They repeat the claim that he has cured or saved the lives of many people whom qualified men have been unable to assist. This kind of claim is one which no known form of judicial proceeding can with confidence establish or refute. Mr. Roche's treatment is not fully disclosed; in the popular, if not in the statutory, sense it is an art and mystery. Perhaps the only adequate method of settling such an issue is one which is unlikely to be attempted—namely, for Mr. Roche's treatment of patients to be examined at close quarters, stage by stage, by a tribunal of experts with full scientific knowledge and full opportunity of inspection. Meanwhile the Society of Apothecaries is in an uncomfortable dilemma. Either it must prosecute the uncertificated practitioner or it must seem to abrogate an important part of its corporate functions. Under English law an Act of Parliament never becomes inoperative through mere disuse; it is alive until it is definitely repealed. If it has outlived its usefulness, and is not supported by popular opinion, magistrates will inflict only negligible or nominal penalties for breach of its provisions. The Apothecaries Act of 1815 has been, and still is, far too valuable to be treated as in any sense obsolete. The Lord Mayor, prompted apparently by what others have told him of Mr. Roche, has intervened in this particular case to dissuade the Society of Apothecaries from taking proceedings. It should, nevertheless, not be assumed that the statute is dead or that its administration is a matter of personal considerations.

UNITED STATES OF AMERICA.

THE WORK OF THE PUBLIC HEALTH SERVICE.

Annual Report of the Surgeon-General.

THE 1928 report of the Surgeon-General of the United States Public Health Service not only summarises all the activities of the Divisions of the Service, but also serves as an index for special reports on much research work. It opens with a survey of health conditions throughout the world. The outbreak of plague in the Argentine was a special menace but only two cases occurred in the States, both being associated with the long-standing infection of the ground squirrels in California. The cholera situation in India is referred to as more serious than in any of the previous eight years except 1924. Cholera did not appear in the United States, but was reported in the Philippines during the summers of 1927 and 1928. Yellow fever appeared in West Africa in June, 1928, after several months' absence. There have been sporadic cases in Brazil and, in 1928, an epidemic in Rio de Janeiro, but it was not reported in the U.S.A., the last outbreak having been in 1905. Small-pox was unduly prevalent in view of the known methods of prevention. In Algeria it was epidemic in serious form; in Russia it was largely a rural disease, owing to the rigid enforcement of vaccination in the towns. In 41 of the States there were in 1925, 1926, and 1927 38,877, 31,534, and 33,750 cases respectively, with 712, 367, and 159 deaths. The experience of Detroit, Minneapolis, and Los Angeles from 1924–26 showed that the virulent type may appear without warning and cause hundreds of deaths in a single city within a few months.

During the summer and autumn of 1927 there was a widespread outbreak of infantile paralysis in the U.S.A., with a high case-fatality. The cases reported in 36 States during the last three years numbered 5585, 2445, and 8808, and the deaths 1335, 728, and 1710, giving a case-fatality of nearly 25 per cent. for the period. The deaths from pellagra (5148) showed an increase, consequent upon unfavourable industrial and economic conditions in the Mississippi valley flood area and other regions. Special researches on the anti-pellagrous properties of various foodstuffs have been made and dried yeast was made available in the flood districts.

Before 1921 the case- and death-rates from diphtheria were rising. From 1921–26 there was an

London) 1·67. In the same week the death-rate from all causes for the 107 great towns was 21·4, the highest figures being Birmingham 24·5 and Sheffield 23·1. More than 20 deaths were still attributed to influenza in the following towns—namely: Birmingham, 93; Sheffield, 52; Bradford, 32; Sunderland, 27; Bristol, 22; Nottingham, 21. In Liverpool 20 deaths were ascribed to measles; 10 in Sunderland. The deaths from whooping-cough remain widely scattered over the country, Manchester heading the list with 14, Liverpool recording 11, Leeds 9, Swansea 8, West Bromwich 7, and Hull 6.

The number of stillbirths registered during the week was 315 (corresponding to a rate of 43 per 1000 births), including 60 in London.

Deaths from Small-pox.—With regard to the death in the county borough of Derby assigned to small-pox by the Registrar-General in the return for the week ended March 16th, Dr. A. E. Brindley, medical officer of health, informs us that the patient was a man aged 61 years, vaccinated in infancy, but not revaccinated. He was the father of a son, aged 27 years, who was removed to the small-pox hospital on Feb. 27th. The man himself was kept under observation and on March 15th was found to be seriously ill by Dr. Haigh, assistant medical officer of health, no other doctor having been in attendance. He died a few hours later, the symptoms being apparently those of the influenzal pneumonic type. He had one or two small-pox spots, and death was certified as (1*a*) pneumonia, (*b*) influenza; (2) small-pox. It is quite possible in this case, Dr. Brindley adds, that the man died from influenzal pneumonia, but if so he had undoubted small-pox at the same time.

A second fatal case, which occurred in the Metropolitan Borough of Finsbury, was that of a male infant aged 8 months, one of twins both unvaccinated, who died rather suddenly on March 8th after having been ill for about two days. Dr. A. E. Thomas, medical officer of health, who saw the body shortly after death, noted blotchy hæmorrhages on both flanks and thighs ranging in diameter from one-eighth to three-eighths inch. Their distribution complied with the known distribution of hæmorrhagic small-pox but the blotches were larger than those usually described. Up to the present no other case of small-pox has occurred in the family or in the house and the diagnosis of hæmorrhagic small-pox is regarded as provisional. The post-mortem examination disclosed no obvious cause of death and there was no inquest.

Provisional Death-rates.

The Registrar-General gives the provisional death-rates per million population for England and Wales during the year 1928, as follows:—

	Males.	Females.	Persons.
Respiratory tuberculosis	879	641	755
Other tuberculosis	188	159	173
Cancer	1377	1469	1425

In the same year the provisional mortality of women in childbirth from puerperal sepsis was 1·80, from other accidents and diseases of pregnancy and parturition 2·63, the ratio in each case being per 1000 live births.

A COUNTRY HOME FOR CHILDREN.—The Carnegie Dunfermline Trustees have acquired Bandrum House, which occupies a commanding site within three miles of Dunfermline, as a home for children who are physically below par. The children will be kept as long as they are likely to be improved or until their powers of resistance are strengthened.

WORK OF THE VOLUNTARY HOSPITALS.—*Victoria Hospital, Kingston-on-Thames:* This hospital is to be enlarged by building a children's ward and a ward for private patients, and a new X ray apparatus is to be installed. —*Royal Portsmouth Hospital:* The annual report emphasises the necessity for separating the medical and surgical cases into separate wards—the overcrowding of the hospital is especially severe on the surgical side. Last year there were 2500 operations and a second theatre is urgently needed.—*Poplar Hospital for Accidents:* The number of in-patients increased from 1604 to 2150. The stay of each patient dropped from 20 to 15½ days. The X ray and massage departments are said to need enlargement and better equipment.—*Cheltenham Hospital:* This institution is being enlarged by the addition of 24 beds, six of which will be reserved for paying patients, and the out-patient department is being extensively remodelled.

Correspondence.

"Audi alteram partem."

X RAY EXAMINATION AFTER INJURY.

To the Editor of THE LANCET.

SIR,—Dr. Gordon Ward raises such an important point that I think his challenge should not go unanswered. I have been a vice-president of the Medical Defence Union for some years, but now have retired, so perhaps I am at liberty to speak. The Union does not give its members ill-considered advice. Through large experience the Union has become by far the best judge as to the danger of any procedure taken, or not taken, by a medical man. The number of cases brought before the Union, in which medical men are charged with negligence for not taking an X ray photograph after an injury, is far in excess of the occasional cases which may come to the notice of the medical practitioners. For when the Union supports its members a large majority of cases are dropped and nothing is heard of them. At the same time the cost of these cases to the Union must be considerable. The worry and distress caused to the doctor is a lesson to anyone who has unfortunately seen it. To omit to take an X ray photograph, and then be sued for negligence, by an unrecovered patient who has for evidence an X ray photograph, taken subsequently and showing a fracture, produces a position almost impossible to get out of unless supported by the Union. If the Union is willing to give its support, its advice should be taken.

A legal opponent in a case of this description knows full well that the chances of finding a fracture are such that an X ray is imperative, and the expense of the photograph more than justified. Why should not the doctor think so too, and be first in the field? From experience at the Union, and in my own work, fractures have been found in many unsuspected cases; especially recently have I found them in the skull. I have found that the advice of the Union is wise, and I have been saved considerable discomfiture thereby. For these reasons I do not think that Dr. Ward should demur at putting a patient to the comparatively small cost of an X ray photograph considering the issues at stake on both sides. Rather would I suggest that he might look upon the time and money spent as an excellent form of insurance both for himself and his patient.

I am, Sir, yours faithfully,
HORACE HILL, M.R.C.P.

Gillingham Green, Kent, April 2nd, 1929.

THE STUDY OF INDUSTRIAL HYGIENE.

To the Editor of THE LANCET.

SIR,—It is well for a culprit to make a full confession of his misdeeds, so I was glad to read Dr. Carozzi's letter in your issue of to-day. The charge was that Dr. Carozzi had strung together the dicta of various writers (some unnamed, all without bibliographical references), the accuracy and relevance of which he had neither appraised nor had sufficient technical knowledge (statistical and other) to appraise.

Dr. Carozzi—angrily, of course, but explicitly—pleads guilty, and even gives us a sketch of himself at work with scissors and a paste pot, joining the opinions of A to the observations of B and the speculations of C. What is it to him whether A's opinions were correct, the observations of B typical, or the speculations of C credible? D finds that 16 per cent. of the deaths known to him were due to tuberculosis, E has found 75 per cent.; F actually finds that from a third to half the living workers examined by him were suffering from pulmonary tuberculosis. What does it matter to Dr. Carozzi that proportional mortality is a function of age distribution and the diagnosis of tuberculosis a function of the standard of examination; what does he care whether like is being compared with like! A, B, C, D, E, and F are "authorities," one adds their several authoritativenesses together and reaches the sham omniscience of the Geneva brochure.

> Non tali auxilio nec defensoribus istis
> Tempus eget.

Every great newspaper has on its staff journalists as competent as Dr. Carozzi, straightforward men not professing to be anything *but* journalists. It is indeed well that Dr. Carozzi should have explained his position.

I am, Sir, yours faithfully,
March 30th, 1929. MAJOR GREENWOOD.

THE EMPLOYMENT OF BACTERIA IN MODERN WARFARE.

To the Editor of THE LANCET.

SIR,—According to newspaper reports, Sir Berkeley Moynihan has publicly repeated the allegation that during the late war plague bacilli were employed by the German Army. Our distinguished colleague might well have been expected to make absolutely sure of his facts before venturing to proclaim such an accusation. Yet not only has our Government solemnly denied having used such methods, but even experts of the allied countries have borne out this statement —e.g., Dr. Paul, head of the French Poison Gas Service. What is more, the employment of bacteria was not even planned! We and our colleagues who were hygienic advisors to the Army in France and Belgium were never consulted on this question from beginning to end of the war.

But quite apart from these considerations, it is obvious to every bacteriologist that pathogenic bacteria are totally unsuitable as implements of warfare, since their action is uncertain, their range of action limited, and the danger to the troops employing them far too great. These arguments were fully stated by one of us (Pf.) in a report made at the request of the League of Nations shortly after the war; they were endorsed by Dr. Thorvald Madsen, President of the Hygiene Organisation of the League of Nations: (1) Owing to their rapid loss of virulence, all pathogenic bacteria cannot be kept at a high and constant level of infectivity. (2) But even assuming this problem to have been mastered, the technique of transmitting the bacteria to the enemy presents insurmountable difficulties. In explosive missiles bacteria would be instantly destroyed by the heat of explosion. (3) If flasks of culture were projected —e.g., from aeroplanes—there is hardly the faintest chance of infecting a few isolated persons, but never of setting up epidemic foci, whilst any bacteria not at once penetrating into the body would speedily die. (4) As regards the idea of infecting rats and letting them loose in the direction of the enemy's lines, this would manifestly be a far greater danger to our own troops, who would thus be "hoist by their own petard."

We can therefore but regret that a man of such high professional standing and knowledge should propound these unfounded and erroneous statements. This is the more to be deprecated because of the harm thus caused to the spirit of mutual understanding and scientific intercourse which is gradually beginning to replace war- and post-war-psychosis. Ten years after the war we Europeans have more serious anxieties than to repeat disproved accusations!

We are, Sir, your obedient servants,
RICHARD PFEIFFER, M.D.Berl., F.R.S.Lond.,
Emeritus Professor of Hygiene in the University of Breslau.

CARL PRAUSNITZ, M.D. Bresl., M.R.C.S. Eng., L.R.C.P. Lond.,
Professor of Hygiene in the University of Breslau.
Breslau, March 24th, 1929.

⁂ The reference is to a remark made by Lord Moynihan at the Authors' Club on Feb. 25th when, as reported in the *Times* of the following day, he said: "We heard in 1916 that the Germans were going to use plague as a lethal weapon and we actually recovered plague bacilli from bombs dropped over the Fifth Army." In the History of the Great War based on Official Documents (Medical Services, Hygiene of the War, Vol. II., 1923) Major T. J. Mitchell, dealing with prevention of plague, stated (p. 458): "On the Western front in February, 1916, it was rumoured that the Germans might use plague as an offensive weapon against the allied armies, but this was considered highly improbable," and (p. 460): "In January, 1918, the D.M.S. of the Fifth Army reported that the mobile laboratory in his area had examined some material dropped by an enemy balloon, and that bacilli resembling the *Bacillus pestis* had been isolated." *We are glad to have* this authoritative assurance from high German sources that no such offensive weapon was used.—ED. L.

GAMMA RADIATION.

To the Editor of THE LANCET.

SIR,—In reply to Sir Charles Gordon-Watson and Mr. Stanford Cade, we had thought it was common knowledge that beta rays will not pass through such screens as we used, and that the length of a container has nothing whatever to do with the nature of the radiations it transmits. It is disappointing that "after careful perusal" of our note our critics failed to discover that we only suggested the use of an old-fashioned method in cases where other measures were inapplicable. We were at pains to state the dosage of gamma rays which produced necrosis and to indicate the dosage which seemed to give the best results.—We are, Sir, yours faithfully,

CECIL P. G. WAKELEY.
HECTOR A. COLWELL.
King's College Hospital, S.E., March 28th, 1929.

The Services.

ROYAL ARMY MEDICAL CORPS.

Maj.-Gen. W. H. S. Nickerson, late R.A.M.C., is placed on half pay.

Col. H. Ensor, late R.A.M.C., to be Maj.-Gen., vice Maj.-Gen. Nickerson.

Lt.-Col. L. M. Purser, from R.A.M.C., to be Col.

Maj. and Bt. Lt.-Col. W. P. MacArthur to be Lt.-Col., vice Lt.-Col. Purser.

Maj. J. T. Simson, from R.A.M.C. Res. of Off., to be Maj.

Temp. Lt. G. F. Maher relinquishes his commn.

Lt. (on prob.) H. E. Knott, from the secd. list, is restd. to the estabt.

ARMY RESERVE OF OFFICERS.

Lt.-Col. F. W. Cotton, having attained the age limit of liability to recall, ceases to belong to the Res. of Off.

TERRITORIAL ARMY.

Lts. G. Tudhope and D. Jack to be Capts.

TERRITORIAL ARMY RESERVE OF OFFICERS.

Lt.-Col. E. J. D. Taylor, having attained the age limit, relinquishes his commn. and retains his rank.

ROYAL AIR FORCE.

Flying Officer E. J. T. McWeeney is promoted to the rank of Flight Lt.

Flying Officer G. M. Titterington (temp. Lt., General List, Army Dental Surgeon) relinquishes his temporary commission in the R.A.F. on completion of service.

INDIAN MEDICAL SERVICE.

Majs. to be Lt.-Cols.—A. J. Lee, C. H. Smith, A. MacD. Dick, M. J. Holgate, T. L. Bomford, W. A. M. Jack, A. C. Anderson, Keshav Sadashiv Thakur, E. H. V. Hodge, G. T. Burke, M. A. Nicholson.

To be Lts. (on prob.).—K. F. Alford, H. J. Curran, H. T. McWilliams, P. Shannon, G. J. O'Connor, B. J. Griffiths, E. A. Y. Mackeown, H. S. Waters, W. P. Lappin, G. Milne, A. M. Fraser, D. L. Trant, and W. Walsh.

Lt.-Col. R. M. Barron retires.

London) 1·67. In the same week the death-rate from all causes for the 107 great towns was 21·4, the highest figures being Birmingham 24·5 and Sheffield 23·1. More than 20 deaths were still attributed to influenza in the following towns—namely: Birmingham, 93; Sheffield, 52; Bradford, 32; Sunderland, 27; Bristol, 22; Nottingham, 21. In Liverpool 20 deaths were ascribed to measles; 10 in Sunderland. The deaths from whooping-cough remain widely scattered over the country, Manchester heading the list with 14, Liverpool recording 11, Leeds 9, Swansea 8, West Bromwich 7, and Hull 6.

The number of stillbirths registered during the week was 315 (corresponding to a rate of 43 per 1000 births), including 60 in London.

Deaths from Small-pox.—With regard to the death in the county borough of Derby assigned to small-pox by the Registrar-General in the return for the week ended March 16th, Dr. A. E. Brindley, medical officer of health, informs us that the patient was a man aged 61 years, vaccinated in infancy, but not revaccinated. He was the father of a son, aged 27 years, who was removed to the small-pox hospital on Feb. 27th. The man himself was kept under observation and on March 15th was found to be seriously ill by Dr. Haigh, assistant medical officer of health, no other doctor having been in attendance. He died a few hours later, the symptoms being apparently those of the influenzal pneumonic type. He had one or two small-pox spots, and death was certified as (1*a*) pneumonia, (*b*) influenza; (2) small-pox. It is quite possible in this case, Dr. Brindley adds, that the man died from influenzal pneumonia, but if so he had undoubted small-pox at the same time.

A second fatal case, which occurred in the Metropolitan Borough of Finsbury, was that of a male infant aged 8 months, one of twins both unvaccinated, who died rather suddenly on March 8th after having been ill for about two days. Dr. A. E. Thomas, medical officer of health, who saw the body shortly after death, noted blotchy hæmorrhages on both flanks and thighs ranging in diameter from one-eighth to three-eighths inch. Their distribution complied with the known distribution of hæmorrhagic small-pox but the blotches were larger than those usually described. Up to the present no other case of small-pox has occurred in the family or in the house and the diagnosis of hæmorrhagic small-pox is regarded as provisional. The post-mortem examination disclosed no obvious cause of death and there was no inquest.

Provisional Death-rates.

The Registrar-General gives the provisional death-rates per million population for England and Wales during the year 1928, as follows:—

	Males.	Females.	Persons.
Respiratory tuberculosis	879	641	755
Other tuberculosis	188	159	173
Cancer	1377	1469	1425

In the same year the provisional mortality of women in childbirth from puerperal sepsis was 1·80, from other accidents and diseases of pregnancy and parturition 2·63, the ratio in each case being per 1000 live births.

A COUNTRY HOME FOR CHILDREN.—The Carnegie Dunfermline Trustees have acquired Bandrum House, which occupies a commanding site within three miles of Dunfermline, as a home for children who are physically below par. The children will be kept as long as they are likely to be improved or until their powers of resistance are strengthened.

WORK OF THE VOLUNTARY HOSPITALS.—*Victoria Hospital, Kingston-on-Thames:* This hospital is to be enlarged by building a children's ward and a ward for private patients, and a new X ray apparatus is to be installed. —*Royal Portsmouth Hospital:* The annual report emphasises the necessity for separating the medical and surgical cases into separate wards—the overcrowding of the hospital is especially severe on the surgical side. Last year there were 2500 operations and a second theatre is urgently needed.—*Poplar Hospital for Accidents:* The number of in-patients increased from 1604 to 2150. The stay of each patient dropped from 20 to 15½ days. The X ray and massage departments are said to need enlargement and better equipment.—*Cheltenham Hospital:* This institution is being enlarged by the addition of 24 beds, six of which will be reserved for paying patients, and the out-patient department is being extensively remodelled.

X RAY EXAMINATION AFTER INJURY.

To the Editor of THE LANCET.

SIR,—Dr. Gordon Ward raises such an important point that I think his challenge should not go unanswered. I have been a vice-president of the Medical Defence Union for some years, but now have retired, so perhaps I am at liberty to speak. The Union does not give its members ill-considered advice. Through large experience the Union has become by far the best judge as to the danger of any procedure taken, or not taken, by a medical man. The number of cases brought before the Union, in which medical men are charged with negligence for not taking an X ray photograph after an injury, is far in excess of the occasional cases which may come to the notice of the medical practitioners. For when the Union supports its members a large majority of cases are dropped and nothing is heard of them. At the same time the cost of these cases to the Union must be considerable. The worry and distress caused to the doctor is a lesson to anyone who has unfortunately seen it. To omit to take an X ray photograph, and then be sued for negligence, by an unrecovered patient who has for evidence an X ray photograph, taken subsequently and showing a fracture, produces a position almost impossible to get out of unless supported by the Union. If the Union is willing to give its support, its advice should be taken.

A legal opponent in a case of this description knows full well that the chances of finding a fracture are such that an X ray is imperative, and the expense of the photograph more than justified. Why should not the doctor think so too, and be first in the field? From experience at the Union, and in my own work, fractures have been found in many unsuspected cases; especially recently have I found them in the skull. I have found that the advice of the Union is wise, and I have been saved considerable discomfiture thereby. For these reasons I do not think that Dr. Ward should demur at putting a patient to the comparatively small cost of an X ray photograph considering the issues at stake on both sides. Rather would I suggest that he might look upon the time and money spent as an excellent form of insurance both for himself and his patient.

I am, Sir, yours faithfully,
HORACE HILL, M.R.C.P.

Gillingham Green, Kent, April 2nd, 1929.

THE STUDY OF INDUSTRIAL HYGIENE.

To the Editor of THE LANCET.

SIR,—It is well for a culprit to make a full confession of his misdeeds, so I was glad to read Dr. Carozzi's letter in your issue of to-day. The charge was that Dr. Carozzi had strung together the dicta of various writers (some unnamed, all without bibliographical references), the accuracy and relevance of which he had neither appraised nor had sufficient technical knowledge (statistical and other) to appraise.

Dr. Carozzi—angrily, of course, but explicitly—pleads guilty, and even gives us a sketch of himself at work with scissors and a paste pot, joining the opinions of A to the observations of B and the speculations of C. What is it to him whether A's opinions were correct, the observations of B typical, or the speculations of C credible? D finds that 16 per cent. of the deaths known to him were due to tuberculosis, E has found 75 per cent.; F actually finds that from a third to half the living workers examined by him were suffering from pulmonary tuberculosis. What does it matter to Dr. Carozzi that proportional mortality is a function of age distribution and the diagnosis of tuberculosis a function of the standard capital, Norwich, where the whole of his professional work was afterwards done. He became house surgeon to the Norfolk and Norwich Hospital, then surgical registrar, and in 1888 was appointed assistant surgeon to the institution. At the same time he became surgeon to the Jenny Lind Infirmary for Children and to the Norfolk and Norwich Eye Hospital. It is interesting to note that he lived and died in Norwich in the same house as the famous William Cadge who, a generation earlier, had occupied a position of high surgical distinction in the city. Burton was the direct follower of Cadge, whose career was necessarily closing just about the time of the former's election to the staff, and his services soon became in constant demand throughout the county both as a consultant and as an operator, his reputation being equally high as general surgeon, ophthalmologist, and accoucheur. At the time of his death he had been for some ten years on the consultant staff, but his period of active service covered no less than 40 years, and the institution gained as much from his administrative ability as from his scientific skill, for he was allowed on all hands to possess a first-rate business sense.

Burton was a deservedly popular man with the public as well as with his professional colleagues, and although his time was almost over-occupied by the demands of his practice, he was both a fisherman and a golfer and a good musician. He is survived by his widow, two sons, and two daughters.

JAMES McHUGH, M.B. LIVERP.

It is with deep regret that we record the sudden death after a brief illness of Dr. James McHugh, of Waterloo. Educated at Liverpool Institute, he entered the medical school of the University in 1922. Possessed of a strong physique, good mental ability, and unusual powers of concentration, he readily achieved the highest honours of a student's career. After being awarded the Derby exhibition in medicine, he graduated in 1927 with first-class honours and distinctions in medicine and surgery. After 12 months' residence at the Royal Infirmary, first as house physician and then as house surgeon, feeling that general practice offered a closer contact with patients and a more human interest than consulting work, he became assistant to Dr. W. R. Rowlands, of Waterloo Park. In the course of his work he contracted pneumonia and died at the Royal Infirmary, after a week's illness, on March 31st. His death has brought to a premature close a career of great promise; he will be missed as a loyal colleague, a charming personality, and a faithful friend.

ROYAL SOCIETY OF TROPICAL MEDICINE AND HYGIENE.—The Manson Medal, awarded triennially, is to be presented this year to Sir Ronald Ross. It was founded in memory of Sir Patrick Manson in 1922 and has been awarded to Sir David Bruce and Senator Ettore Marchiafava. Qualifications for the medal are contributions of outstanding merit to knowledge of tropical medicine and hygiene.

The Chalmers Medal was founded in 1921 by Mrs. Chalmers in memory of her husband, Dr. Albert J. Chalmers. It is awarded every second year to a worker in the field of tropical medicine and hygiene who must be under 45 years of age on June 1st of the year of award. It is to be presented this year to Major J. A. Sinton, V.C., I.M.S. Previous awards have been made to Prof. E. Roubaud, Prof. Warrington Yorke, and Dr. H. Lyndhurst Duke.

Though the Manson Medal was founded in memory of Sir Patrick Manson, an attempt is being made to found a more substantial memorial in the shape of a permanent home for the society. To this end the Manson House Fund was started, and already subscriptions have brought in between four and five thousand pounds, while three thousand pounds have been promised on loan without interest. It is hoped that a sufficient sum will be raised to enable the society to purchase suitable premises which will form its headquarters. Sir Patrick Manson was the first president.

Parliamentary Intelligence.

NOTES ON CURRENT TOPICS.

THE EASTER RECESS.

PARLIAMENT adjourned for the Easter Recess on Wednesday, March 27th. The Royal Assent was given to the Local Government Act, the Factories and Workshops (Cotton Cloth Factories) Act, and other Acts. The House of Commons will reassemble on April 15th and the House of Lords on the 16th.

RECONSTITUTED CREAM BILL.

In the House of Commons on March 26th, on the motion for the third reading of the Reconstituted Cream Bill, a measure designed to prevent reconstituted cream being sold to the public as farm cream,

Mr. A. V. ALEXANDER said that to the general idea of the Bill the Opposition had no objection. If tradesmen in general were offering for sale as cream something which was not cream direct from the farm the public were entitled to know. Grave difficulties would, however, be set up for the tradesmen who would be using the reconstituted article to take the place of cream which they could no longer get in satisfactory quantities to keep for the length of time necessary for their manufacturing purposes. There was nothing in the Bill to prevent the public from believing that they were getting, either direct or in restaurants, actual cream, when what they actually were getting was really much inferior in its constituents to reconstituted cream. The Bill did nothing to protect the public against substitutes for cream which were most injurious to them.

Sir KINGSLEY WOOD (Parliamentary Secretary to the Ministry of Health) said Mr. Alexander had based his opposition to the Bill mainly on the ground that it did not apply to what was called synthetic cream. But that substance was already provided for under the Food and Drugs (Adulteration) Act, and therefore there was no need for any provision covering it in this measure. This Bill provided that the surplus milk of the country should be used, but used honestly. If milk was used to make what was known as reconstituted cream it was only fair that the general public should know what they were receiving and paying for.

The Bill was read the third time and passed.

HOUSE OF LORDS.

TUESDAY, MARCH 26TH.

LOCAL GOVERNMENT (SCOTLAND) BILL.

THE House went into Committee on the Local Government (Scotland) Bill, the Earl of DONOUGHMORE in the chair.

Transfer of Certain Functions to County Councils.

On Clause 2 Lord ARNOLD moved a new proviso to the effect that public health functions should not be transferred from a Royal burgh or from a burgh with a population of 10,000 and upwards unless not earlier than one year from the passing of the Act such a burgh was certified by the Central Department to be inadequately equipped for administering such functions. He said that there was no such provision in the English Bill. Under this Bill the conduct of health services was being taken away from small burghs and handed over to the county councils. In England 400 such small communities with populations under 5000 were administering identical, or very similar, functions.

The Earl of ONSLOW (Paymaster-General) said that it was quite true that these small burghs had done their work very well indeed, but the policy of the Bill was to transfer the wider functions to reconstituted county councils in order to make them of adequate resource and strength for their new duties. This amendment would cut at the roots of the Bill, because it aimed not only at efficiency, but at simplicity in administration.

The amendment was by leave withdrawn.

Medical Officers of Health and Sanitary Inspectors.

On Clause 35 Viscount YOUNGER OF LECKIE moved an amendment to make it compulsory that where there was a vacancy in the office of medical officer of health in a small burgh the county medical officer of health should be at once appointed to the vacancy.

The Marquess of SALISBURY (Lord Privy Seal) said that he did not deny that very often the arrangement suggested by Lord Younger might be by far the best one. But it seemed to the Government that it would be a pity to make it absolutely compulsory in every case, and some kind of power should be left to the Secretary of State to see that in particular cases where the circumstances were such that the appointment of a special man might be good for the burgh it should not be compulsory that the county medical officer should be appointed to the vacancy. If the noble lord was not satisfied he would look into the point before the report stage and see if any more could be done.

Viscount YOUNGER OF LECKIE said that he thought that it was clearly desirable that the medical officer of health for the county should have supervision over the whole of these burghs. The continuation of these officers in small burghs was a great mistake and very expensive.

The amendment was by leave withdrawn.

On Clause 72, which enables the Secretary of State to make

Orders for Bringing the Act into Operation,

the Marquess of SALISBURY said that on the second reading of the Bill he had expressed his assurance that the Government were not averse to considering modifications of the clause as originally drafted. They were quite willing to strike out Subsection 1 which gave the Secretary of State power to modify this Bill in any respect he might hereafter think necessary in order to bring the machinery into operation. There was much criticism against such sweeping powers, and the Secretary of State had come to the conclusion that it was not really necessary to have that power at all. The Government were therefore willing to delete the subsection. Subsection 2 was not quite the same, as it provided power to modify other Acts of Parliament which might be difficult to adjust with respect to this particular Bill. In determining the protection given in that case the Government had naturally looked to the provision put by their lordships into the English Bill. That protection consisted of an affirmative resolution; the changes sought to be made by the Order of the Secretary of State did not operate except for a short time unless by affirmative resolution of both Houses of Parliament in favour of the change. In addition they did not desire that this power of modifying Acts of Parliament should be perpetual, and they provided that an Order of this kind should only be possible up to the end of 1930. What remained was the power to modify local Acts of Parliament, and the Government must adhere to the original proposals in that limited jurisdiction, because the local Acts of Parliament were very numerous and they had no means of ascertaining what they were.

Amendments were inserted in the Bill to carry out the intentions of the Government in accordance with Lord Salisbury's statement.

The Committee stage of the Bill was concluded and the Bill was reported as amended to the House.

HOUSE OF COMMONS.

TUESDAY, MARCH 26TH.

Deaths from Coal-gas Poisoning.

Mr. BOWERMAN asked the President of the Board of Trade whether his attention had been drawn to the fact that during the past 15 years deaths due to coal-gas poisoning had increased from 170 to 1142; that during that period the percentage of carbon monoxide, the chief poisonous contituent of coal-gas, had been raised from 7 per cent. to as much as 15 per cent., and in some cases to 20 per cent., such increase militating against the recovery of persons accidentally poisoned by gas; and whether he was prepared to give consideration to the recommendation of the committee appointed in 1921 to the effect that if the freedom from limitation in the use of carbon monoxide was proved to be accompanied by unexpectedly unfavourable results, the attention of Parliament should again be directed to the matter.—Sir P. CUNLIFFE-LISTER replied: My attention has been directed to the statistics of gas poisoning cited by the right hon. Member, and more particularly since the Report of the Committee on Carbon Monoxide in 1921. The situation has been carefully watched and relevant information collected. When reference is made to the number of deaths due to gas poisoning it is necessary to bear in mind how large a proportion are cases of suicide. But I think that it would be desirable that a small but experienced committee should review the developments which have taken place since the Pearce Committee sat in 1921; and I propose to appoint such a committee.

Outrages on Women in Trains.

Mr. MORRIS asked the Minister of Transport whether his attention had been drawn to the number of outrages committed upon women in non-corridor trains; and would he make representations to the railway companies that all passenger trains should have corridor carriages only.—Colonel W. ASHLEY replied: So far as my information goes deplorable incidents such as those to which the hon. Member refers are of rare occurrence. I am not prepared to press railway companies to discontinue entirely the use of non-corridor stock, but I will call their attention to the hon. Member's suggestion.

Milk for Public Health Purposes.

Mr. POTTS asked the Minister of Health whether he would introduce immediate legislation to amend the law so as to ensure that every purchaser of milk should be supplied with milk containing not less than a legal standard of milk fat and milk solids, other than milk fat, relating to services for the treatment of tuberculosis, maternity, and child welfare, &c., administered by public authorities under the Public Health Acts.—Sir KINGSLEY WOOD replied: Apart from any question as to the practicability of the proposal, my right hon. friend could not undertake to introduce legislation on the subject at the present time.

WEDNESDAY, MARCH 27TH.

The London Lock Hospital.

Viscountess ASTOR asked the Minister of Health what changes in administration he was proposing as a result of the recommendations of the report of the committee of inquiry into the London Lock Hospital; and whether the constitution of the board of management had been so changed as to give a greater choice of women.—Sir KINGSLEY WOOD replied: As indicated in reply to questions on this subject on March 14th the hospital is a voluntary institution, and reponsibility for carrying recommendations of the Committee into effect rests, not with my right hon. friend, but with the board of the hospital. My right hon. friend has not yet received specific proposals from the board as to their reconstitution, but he understands that they contemplate the inclusion of women on the board in future.

Public Health Conference at Zurich.

Mr. HARRIS asked the Minister of Health why he had refused to sanction the attendance of delegates from municipal councils to the forthcoming conference in Zurich of the Royal Institute of Public Health.—Sir KINGSLEY WOOD replied: My right hon. friend has given careful consideration to the application of the Institute in this matter and he does not feel satisfied that benefits commensurate with the considerable expense involved would be obtained by the attendance at the cost of the rates of delegates from local authorities at the conference.

National Health Insurance.

Mr. KELLY asked the Minister of Health the number of men, women, and young persons insured under the National Health Insurance Act at the end of 1928.—Sir KINGSLEY WOOD replied: The number for Great Britain is estimated to be 16,950,000, of whom 11,550,000 are men and 5,400,000 are women. These numbers include 790,000 persons who, having reached 65 years of age, have ceased to pay contributions under the Act and to be entitled to sickness and disablement benefits.

Grant to British Social Hygiene Council.

Captain CROOKSHANK asked the Secretary of State for the Colonies what, if any, conditions were attached to the grant of £500 made to the British Social Hygiene Council; and whether the grant was made after consultation with the Minister of Health.—Mr. AMERY replied: This grant is made to assist the Council in organising propaganda work in the Colonies, &c. Its employment is limited to certain specified services, such as the supply of films and medical and educational literature. Payments out of the grant are made only in reimbursement of certified expenditure on approved services. The grant has not recently been the subject of discussion with the Minister of Health, who has no responsibility for work of this kind in the Colonies.

Medical News.

SOCIETY OF APOTHECARIES OF LONDON.—At recent examinations the following candidates were successful:—

Surgery.—K. Girgis (Sect. II.), Manchester and Charing Cross Hospital; D. H. Haler, King's College Hospital; H. H. Lakin, Birmingham and London Hospital; and A. W. Tam, Singapore and Edinburgh.
Medicine.—A. Clark, Glasgow and London Hospital; J. M. Connor, St. Mary's Hospital; R. W. Goldsbrough, Leeds; and R. W. Scanlon, St. Thomas's Hospital.
Forensic Medicine.—R. W. Goldsbrough, Leeds; R. K. Nandlal, Birmingham; and K. M. Seedat, Charing Cross Hospital.
Midwifery.—I. M. Iddali and V. R. D. Lahaumi, Manchester; J. E. Moody, St. Mary's; Z. Risk, Birmingham; A. W. Tam, Singapore and Edinburgh; and E. O. Watson, St. Bartholomew's Hospital.

The Diploma of the Society was granted to the following, entitling them to practise medicine, surgery, and midwifery: J. M. Connor, K. Girgis, D. H. Haler, and R. W. Scanlon.

UNIVERSITY OF ABERDEEN.—At a graduation and diplomas ceremony on March 27th the following degrees were conferred:—

LL.D. (Hon.).—Major Walter Elliot, M.B., M.P.
M.D.—*In absentia:* *E. G. A. Don and *C. R. Philip.
In person: *W. E. McCulloch, A. W. Badenoch, H. B. Cook, Duncan McLellan, W. F. Munro, and S. S. Proctor.

*Awarded Commendation for Thesis.

M.B. Ch.B.—H. M. Trethowan (with Second-class Honours). W. H. Anton, N. D. Begg, Allan Brebner, Elizabeth R. Cairns, T. W. F. Cameron, Donald Fraser, H. C. R. Gunter, Ali Hassan, Grace Krogh, I. M. Munro, D. B. Robb, D. S. Smith, L. M. Watson, J. P. Weir, J. C. Wishart, and A. P. Youngson.

D.P.H.—R. J. Clark, Victoria C. Ensile, A. M. Fraser, and J. S. Harper.

UNIVERSITY OF DURHAM.—At a Convocation on March 22nd *the following degrees were conferred* :—

M.B., B.S.—Andrew Davis, Katharine M. Girling, J. A. Lennox, D. C. Livingston, William Mair, J. H. F. Pankhurst, J. H. Pool, J. W. M. Stevenson, and Howard Willcox.

At recent examinations the following candidates were successful :—

THIRD EXAMINATION FOR M.B., B.S.

Pathology and Bacteriology; Materia Medica, Pharmacology and Pharmacy; Public Health; Medical Jurisprudence.—R. H. Clayton.

The same subjects with General Principles of Therapeutics.—*J. K. Stanger, H. H. D. Anderson, A. G. Craven, Edna T. Everdell, P. N. Grinling, Lily Haugh, J. R. Hindmarsh, William Hunter, Kathleen N. W. Kearney, Gwendoline M. Langham-Hobart, W. D. McF. Millar, Thelma Mouat, Samuel Olswang, H. J. Peters, J. D. Rose, W. G. A. Swan, F. H. Taylor, and J. E. Wilson.

* Second-class honours.

Sir William Prout has relinquished his appointment as Consulting Physician to the Colonial Office and the Crown Agents for the Colonies. Dr. Philip Manson-Bahr has been appointed one of the Consulting Physicians in London.

FOOD EDUCATION SOCIETY.—Dr. Harry Campbell will lecture on Common Errors in Diet at 20, Gordon-square, London, W.C., at 3 P.M. on Wednesday, April 10th, and at week later at the same hour and place Mr. Charles Hecht, hon. secretary of the Society, will speak on Aids to Fitness.

CENTRAL ASSOCIATION FOR MENTAL WELFARE.—A Conference on Mental Welfare will be held, under the auspices of this Association, in the Central Hall, Westminster, on Thursday, April 25th, and Friday, the 26th. The Conference will be opened by Mr. Neville Chamberlain, the Minister of Health, and the speakers will include Mr. L. G. Brock, chairman of the Board of Control; Dr. A. F. Tredgold, and Dr. Ralph Crowley. Application for the full programme and for tickets should be made to the hon. secretary of the Association, 24, Buckingham Palace-road, London, S.W. 1.

HOSPITALS AND MOTOR ACCIDENTS.—In consequence of a suggestion made by Sir Arthur Stanley the Royal Automobile Club is organising a fund for the benefit of hospitals especially affected by road accidents. The money will be distributed without deductions for expenses in collaboration with the British Hospitals Association.

Medical Diary.

Information to be included in this column should reach us in proper form on Tuesday, and cannot appear if it reaches us later than the first post on Wednesday morning

SOCIETIES.

ROYAL SOCIETY OF MEDICINE, 1, Wimpole-street, W.

MONDAY, April 8th.—4.30 P.M., WAR. Annual General Meeting: Election of Officers and Council. Discussion on Functional Diseases of the Nervous System. Opener: Colonel J. C. Kennedy, R.A.M.C. To be followed by Surgeon Rear-Admiral E. T. Meagher, R.N., and Squadron Leader M. L. Burton.

TUESDAY.—5 P.M., ORTHOPÆDICS. Papers: Mr. W. H. Ogilvie: Recent American Papers on Bone Tumours. Mr. R. Watson-Jones: Wrist Dislocation with Associated Nerve Lesions. To be followed by a discussion. 8 P.M., PSYCHIATRY. Joint Meeting with the British Psychological Society (Medical Section). Discussion: The Rôle of Anxiety in the Psychoses and Psychoneuroses. Speakers: Dr. Ernest Jones, Dr. H. Yellowlees, Dr. R. D. Gillespie, and others.

THURSDAY.—8.30 P.M., NEUROLOGY. Discussion on Disseminated Encephalomyelitis.

SOCIETY FOR THE STUDY OF INEBRIETY.

TUESDAY, April 9th.—4 P.M. (in the Rooms of the Medical Society of London, 11, Chandos-street, Cavendish-square, W.), Dr. John Davy Rolleston will open a discussion on Alcohol in Therapeutics.

LECTURES, ADDRESSES, DEMONSTRATIONS, &c.

ROYAL NORTHERN HOSPITAL, Holloway-road, N.

TUESDAY, April 9th.—3.15 P.M., Mr. A. M. Zamora: Hoarseness.

CENTRAL LONDON THROAT, NOSE AND EAR HOSPITAL, Gray's Inn-road, W.C.

WEDNESDAY, April 10th.—1.30 P.M., Examination and Diagnosis of the Nose.

FRIDAY.—4 P.M., Mr. A. Ryland: The Musculature of the Vocal Cords.

ROYAL DENTAL HOSPITAL OF LONDON POST-GRADUATE LECTURES, Leicester-square, W.C.

WEDNESDAY, April 10th.—6 P.M., Mr. *Bowdler Henry*: Lecture Demonstration on Diathermy in Dental Surgery.

NORTH-EAST LONDON POST-GRADUATE COLLEGE, Prince of Wales's General Hospital, Tottenham, N.

MONDAY, April 8th.—2.30 to 5 P.M.: Medical, Surgical, and Gynæcological Clinics. Operations.

TUESDAY.—2.30 to 5 P.M.: Medical, Surgical, Throat, Nose and Ear Clinics. Operations.

WEDNESDAY.—2.30 to 5 P.M.: Medical, Skin, and Eye Clinics. Operations.

THURSDAY.—11.30 A.M.: Dental Clinics. 2.30 to 5 P.M.: Medical, Surgical, and Ear, Nose and Ear, Nose and Throat Clinics. Operations.

FRIDAY.—10.30 A.M.: Throat, Nose and Ear Clinics. 2.30 to 5 P.M., Surgical, Medical, and Children's Diseases Clinics. Operations.

ANCOATS HOSPITAL POST-GRADUATE LECTURES, Mill-street, Manchester.

THURSDAY, April 11th.—4.15 P.M., Dr. Twining: X Ray Findings in Diseases of the Chest.

MANCHESTER ROYAL INFIRMARY POST-GRADUATE COURSE.

TUESDAY, April 9th.—4.15 P.M., Mr. J. P. Buckley: Pain after Food.

FRIDAY.—4.15 P.M., Mr. E. D. Telford: Demonstration of Surgical Cases.

Appointments.

FERGUSON, J., M.B., B.Ch. R.U.I., D.P.H., has been appointed County Medical Officer for Surrey.

McMAHON, A. D., M.B., B.Ch. N.U.I., D.P.H., County Medical Officer of Health for Carlow.

ROBERTS, D. R., M.B. Durh., Certifying Surgeon under the Factory and Workshop Acts for the New Tredegar District of Monmouth.

Salford Royal Hospital: THORNTON, T., M.B., Ch.B. St. And.; and MAXWELL, R. J. C., M.B., Ch.B. Belf., House Surgeons.

Vacancies.

For further information refer to the advertisement columns.

Aberdeen Royal Infirmary.—Jun. Asst. Ophth. Surg.
Altrincham General Hospital.—H.S. At rate of £105.
Ascot Heatherwood Hospital.—Res. Asst. M.O. £300.
Ashton-under-Lyne, District Infirmary.—H.S. At rate of £150.
Ayr County Hospital.—Sen. Res. H.S. At rate of £100.
Bath, Royal United Hospital.—Asst. H.S. At rate of £100.
Bedford County Hospital.—H.S. At rate of £175.
Birmingham, Selly Oak Hospital.—Cas. O. At rate of £200.
Bolingbroke Hospital, Wandsworth Common, S.W.—H.P. At rate of £120.
Bombay, Goculdas Tejpal Hospital.—Hon. Surgeon. Rs.150 per mensem.
Bootle County Borough.—Asst. Sch. M.O. &c. £600.
Brighton, Royal Sussex County Hospital.—Cas. H.S. £120.
Bury St. Edmunds, West Suffolk General Hospital.—H.S. £150.
City of London Hospital for Diseases of the Heart and Lungs, Victoria Park, E.—H.P. At rate of £100.
Colchester, Essex County Hospital.—H.S. £175.
Connaught Hospital for Walthamstow, &c., Orford-road, Walthamstow, E.—Res. H.P. and Res. H.S. Each at rate of £100.
Denbigh, North Wales Sanatorium.—Third A.R.M.O. £250.
Derby, Derbyshire Royal Infirmary.—H.P. £150.
Gravesend and North Kent Hospital.—Jun. H.S. £80 to £200.
Guy's Hospital Dental School, S.E.—Director of the Dental Prosthetic Laboratory. £600.
Halifax Royal Infirmary.—Third H.S. At rate of £100.
Hamilton County Orthopædic Hospital, Stonehouse.—Res. M.O. £600.
Hampstead General and North-West London Hospital, Haverstock Hill, N.W.—H.S., Cas. M.O. Also Cas. Surg. O. Each at rate of £100.
Hospital for Consumption, &c., Brompton, S.W.—Asst. Res. M.O. £150. Jun. H.P. at Frimley Sanatorium. £100. Also H.P. £50 for six months.
Huddersfield Royal Infirmary.—Jun. H.S. £150.
Hull Royal Infirmary.—Hon. Phys.
Isleworth, Warkworth House Institution, &c.—Res. Asst. Med. Supt.
Leicester Royal Infirmary.—Two Surg. Dressers. 10*s.* 6*d.* weekly.
Liverpool City.—Asst. City Bacteriologist. £600.
Liverpool Heart Hospital.—Hon. Asst. Phys.
London Female Lock Hospital, 283, Harrow-road, W.—H.S. At rate of £150.
Manchester, Ancoats Hospital.—Res. Surg. O. £200.
Manchester Hospital for Consumption, &c.—Hon. Asst. Anæsthetist.

Manchester, Salford Royal Hospital.—Res. Surg. O. At rate of £200.

Manchester, Victoria Memorial Jewish Hospital, Cheetham.—Jun. H.S. At rate of £125.

Metropolitan Hospital, Kingsland-road, E.—Sen. H.P. and H.S., Jun. H.P. and H.S. Also two Cas. O.'s. Each at rate of £100.

Miller General Hospital, Greenwich-road, S.E.—Cas. O. £150.

Newcastle-upon-Tyne, University of Durham College of Medicine.—Asst. in Public Health Labs., &c. £350–£450.

New Delhi, India, Lady Hardinge Medical College.—Prof. of Anatomy. Rs. 750 a month.

Northampton Education Committee.—Asst. School Dentist. £450.

Norwich, Norfolk and Norwich Hospital.—H.P. £120.

Nottingham, Bagthorpe Institution and Infirmary.—Res. Asst. M.O. At rate of £300.

Preston, High Carley Sanatorium, near Ulverston.—Asst. Tuber. M.O. £350.

Preston and County of Lancaster, Queen Victoria Royal Infirmary. Hon Asst. S. and Hon. Asst. P.

Prince of Wales's General Hospital, Tottenham, N. — Res. Sen. H.P. Sen. H.S. and Special H.S. Each at rate of £120. Also Jun. H.P. and Jun. H.S. Each at rate of £90.

Queen's Hospital for Children, Hackney-road, E.—Surg. to Ear, Nose and Throat Dept. Cas. O. At rate of £100. Also H.P. At rate of £100.

Reading, Royal Berkshire Hospital.—Med. Reg.

Redhill, Surrey, Royal Earlwood Institution.—Jun. Asst. M.O. At rate of £250.

Romford Union, Oldchurch Hospital.—Res. 2nd Asst. M.O. £250.

Royal Air Force.—Medical Officers.

Royal London Ophthalmic Hospital, City-road, E.C.—Gifford Edmonds Prize in Ophthalmology. £100.

Royal Waterloo Hospital for Children and Women, Waterloo-road, S.E.—H.S. At rate of £100.

St. Andrews Hospital, Devons-road, Bow, E.—Two Asst. M.O.'s. Each £350.

St. John's Hospital, Lewisham, S.E.—Res. M.O. £200. Res. Cas. O. and Jun. H.S. Each at rate of £100.

Saint Mark's Hospital for Cancer, &c., City-road, E.C.—H.S. At rate of £75.

Sheffield Union Hospital, Firvale.—Res. Asst. M.O. £250.

Sunderland Union.—District Medical Officer. £185.

Swansea Hospital.—H.S. £150.

Victoria Hospital for Children, Tite-street, Chelsea, S.W.—Hon. P. or S. for Diseases of the Skin.

Wakefield, Clayton Hospital.—H.S. £150.

Warrington Infirmary and Dispensary.—H.P. £150.

West End Hospital for Nervous Diseases, Welbeck-street, W.—Two Hon. Anæsthetists.

Western Skin Hospital, 44, Hampstead-road, N.W.—Hon. Asst. Dermatologist.

Winchester, Royal Hampshire County Hospital.—Hon. Phys.

The Chief Inspector of Factories announces the following vacant appointment for Certifying Factory Surgeon:—Lytham (Lancs.).

The Secretary of State for the Home Department gives notice of a vacancy for a Medical Referee under the Workmen's Compensation Act for the Bradford, Keighley, Skipton, and Settle County Courts. Applications should reach the Private Secretary, Home Office, Whitehall, S.W., not later than April 17th.

Births, Marriages, and Deaths.

BIRTHS.

ANGUS.—On March 27th, at Bewick-road, Gateshead, the wife of Dr. Alan Angus, of a daughter.

BARDSLEY.—On March 27th, at Carlton-road, Putney, the wife of Dr. P. E. Bardsley, of a son.

BENJAMIN.—On March 27th, the wife of Dr. Alva Benjamin, of a daughter.

FETTES.—On March 22nd, at Randolph-crescent, Edinburgh, the wife of Major D. Fettes, R.A.M.C., of a son.

HUBBLE.—On March 23rd, at Derby, the wife of Douglas Hubble, M.B., B.S., of a daughter.

SMITH.—On March 20th, at "Cullingworth," St. Peter's-in Thanet, the wife of R. Wylie Smith, M.B., B.Chir., of a daughter.

SNELL.—On March 28th, at Altrincham, Cheshire, to Evelyn, wife of Norman Snell, M.D.—a son.

MARRIAGES.

MINDE—WILSON.—On March 9th, at Chelsea Register Office, Dr. Max Minde, of Horrsal, Cape Town, and London, to Valerie Frances Somerville Wilson, of Arlington, Johannesburg, South Africa.

DEATHS.

ATKINS.—On March 25th, suddenly, at Chelston Manor, Torquay, Frederick Durnford Atkins, M.B., B.S., M.R.C.S., L.R.C.P.

BURTON.—On March 30th, at St. Giles-street, Norwich, Samuel Herbert Burton, M.B., F.R.C.S. Eng., J.P., aged 75.

HEDDEN.—On March 28th, at South Bank, Bideford, Richard Hedden, M.R.C.S. Eng., L.R.C.P. Lond., L.S.A., aged 68.

HUNT.—On March 22nd, at Maidenhead, Edwin Guy Hunt, M.D., of Erpingham-road, Putney.

STEELE.—On March 25th, at Clifton, Bristol, Lieut.-Colonel W. H. Steele (retired), R.A.M.C.

WHITE.—On Good Friday, Edward Augustine White, M.B., B.S., M.R.C.S., L.R.C.P. Lond., aged 25 years.

N.B.—A fee of 7s. 6d. is charged for the insertion of Notices of Births, Marriages, and Deaths.

Notes, Comments, and Abstracts.

MANIPULATION OF THE BACK.*

BY JAMES MENNELL, M.D. CAMB.,
SENIOR MEDICAL OFFICER OF THE KENSINGTON CENTRE FOR PHYSICAL TREATMENT, BRITISH RED CROSS SOCIETY.

THE Clinic of the Kensington division of the British Red Cross Society's Centre for Physical Treatment was used originally during the war for the treatment of soldiers. Later on, it became a clinic for the treatment of pensioners. When these services were no longer required, those responsible decided that, if it had held a useful place in the treatment of soldier and pensioner, it might surely do so in the treatment of the civilian populace.

The Kensington Red Cross Centre.

Like other institutions of a similar kind, it opened with a few—literally two—patients. During the seven years of its existence there have been 4180 patients on the books. There has been an average daily attendance of 88 patients for treatment during the last six months, and the average number of new cases received has been 21·15 per week during this period. The clinic has grown in part, of course, through the loyal support of some of the practitioners of the neighbourhood, but for the most part patients come through mouth to mouth recommendation from former patients—though I would emphasise the fact that in no circumstances is anyone treated at this clinic unless he or she brings an introduction from a qualified medical practitioner. Those who are in a position to pay for expert advice and treatment elsewhere are also refused, and at the other end of the scale those who cannot pay the minimum fees without financial inconvenience. The comparatively well-to-do and the ordinary hospital out-patient are thus excluded. Between these two classes there is an enormous mass of the populace who cannot afford fees for private treatment, and yet who would shrink from attending hospital, and it is for the sake of these that the clinic exists, and for those who, but for the facilities we give for evening treatment, would be faced with the choice between going without treatment or going on the "sick-list." At the present time there is a loss of about £1000 a year, every penny of which is raised by the Kensington Division of the British Red Cross Society; and, when it is remembered that the wealth of Kensington is far from what it used to be, the courage of those who have made themselves responsible for the clinic becomes obvious.

Every patient who attends there is treated in every respect as an ordinary private patient. The time for consultations with the physician-in-charge is fixed, and the masseuse then reserves a definite time for the patient to attend for treatment. Every patient is treated in a cubicle and is interviewed in just the same way as would be an ordinary private patient. On alternate months throughout the winter a meeting is held at which some one branch of the professional activities carried on at the clinic is described, and all qualified medical practitioners are welcome to attend these meetings.

Physico-therapy of the Spinal Column.

I realise that many people will consider that I am treading on unhallowed ground when claiming manipulations of the spine as a therapeutic agency. There exists in the lay mind a certain amount of confusion of thought about the back. There is something mysterious about it, doubtless connected with the fact that so important a part of the main central nervous system is situated in this region. It is not easy for the layman to realise the difference between the spinal column and the spinal cord, and I am afraid that the power to differentiate between these two has, to a certain extent, pervaded the ranks of our own profession. The spinal cord is part of the central nervous system: the spinal column is part of the skeletal system. Apart, therefore, from considering the back in terms of the central nervous system, the physicotherapist regards it merely in the light of a series of bones and joints. The joint surfaces are of an extremely complicated nature in many situations, particularly in the upper part of the neck and in the pelvic region.

Everyone is, I think, agreed that the spinal column, in so far as it consists of bone, is liable to all the ills of bone in other parts of the body. For instance, we recognise without surprise, malignant disease, tuberculous disease, osteitis deformans, and other bone diseases, but somehow or another the possibility that the joints in the back should suffer in the same way as joints in any other part of the body seems to have been all too frequently overlooked. For example, we are all of us familiar with, and diagnose without question, a synovitis of the knee following on a severe twist. Surely it is possible that a similar lesion should produce a similar condition in one of the spinal joints, and yet, so far as I am aware, I never yet remember hearing the diagnosis given, or even suggested, in the case of a spinal joint. Moreover, we all know and recognise the pain and disability that adhesions may cause in a shoulder-joint, and we take the utmost care and patience to remedy them; yet if a similar condition occurs in one of the spinal joints, the chances are that the patient will be expected to work off his symptoms, while comparatively few are ready to prescribe the treatment which they would so readily prescribe for the knee—namely, that the adhesions should be broken down by joint manipulation under an anæsthetic.

---

* Being the substance of a lecture demonstration on the occasion of the seventh anniversary of the Kensington division of the British Red Cross Society's Centre for Physical Treatment.

The whole situation seems to me to be irrational. If once we admit that the spinal column consists of bones and joints, we must admit that these joints are liable to ordinary strains of accident; and, if we once admit this, we must admit also the essential desirability of making a diagnosis in the first place, and of providing suitable and adequate treatment in the second. We all know how utterly and totally impossible it is to remedy certain cases of stiff shoulder or stiff knee, except by manipulation. So, too, there are countless cases of back trouble where manipulation alone offers a chance of relief, and the tragedy is that no other treatment can possibly be of any avail.

Where a joint is concerned there are only three things which it is possible to do with it. One is to fix it, the second is to move it, and the third course lies between these two—namely, to limit the movement of the joint by support. True, a great deal can be done, by encouraging muscle action, to build up the strength of the muscles which control the movement of joints: but those of you who have tried to build up the strength of a quadriceps which controls a knee, in which full extension cannot be obtained, know only too well the futility of the attempt. Similarly, it is irrational to suppose that, if there is a painful limitation of movement of a joint in the back, the patient of his own volition is able to build up once more the strength of the muscles which control that joint.

The Locking of Joints.

Now we come on to much more delicate ground, and this involves the question as to whether it is possible for a joint to lock or not. I think that few of us who devote any great part of our professional life to the treatment of injuries will fail to accept the fact that locking, to a greater or less degree, can take place in many joints. One of the classical examples is recognised—the case of the "pulled elbow," in which the radius is pulled downwards in the long axis of the forearm, until either the superior or inferior radio-ulnar joints become partially locked. The treatment, of course, is simple, and consists of pushing the radius up again, and this is one of the "five-minute miracle cures" which so delight the heart of the unqualified practitioner of joint manipulation. The same applies to wrist injuries at games like tennis or golf, and more rarely to one of the conditions which are so commonly classed under the generic term of "tennis-elbow." Frequently the most disabling conditions in elbow or wrist, so far as the continued practice of the game in question is concerned, can be relieved instantaneously by manipulation. If the lesion is seen in the early stages, it is quite impossible that adhesions should have formed, and when manipulation cures in these early stages it cannot be due to the breaking down of adhesions. There is no demonstrable dislocation either clinically or on X ray examination, and we can therefore only conclude that, in these cases of recent injury in which manipulation is immediately successful in restoring painless movement, the condition must have been due to a locking of two joint surfaces, and that this locking is freed by the manipulation. If this applies to the joints of the extremities, a most casual glance at, shall we say, the lumbo-sacral junction will serve to show how far more likely is this locking to occur in this situation than in many of the joints of the extremities. This frequently accounts for that endless tale of patients who suffer from backache and, having failed to secure relief through the more recognised channels, have been driven to consult the bone-setter or the osteopath, and have received almost, if not quite, immediate relief.

I do not mean to say that all cases of backache can be relieved by manipulation. The only point I wish to stress is this, that we cannot wilfully blind ourselves and deny that cases do exist in which the symptom of pain in the back is cured by manipulation; and if these do exist, it is our duty to try to distinguish these cases, and to prescribe the only treatment which can possibly be of benefit. Since the war, many discussions have been held upon backache due to various lesions or conditions in the region of the sacro-iliac joint, or of the lumbo-sacral junction. In America the literature on these subjects is voluminous. Quite irrationally, however, as it seems to me, the possibility of trouble arising from acute or chronic conditions in the joints higher up in the back has been entirely ignored.

Take, for example, cases of spasmodic torticollis in the adult—that terribly distressing condition which one usually only encounters in those of advancing years. Life to these poor sufferers is rendered wellnigh intolerable, and the only thought that they have to comfort them is that life itself cannot continue very much longer. On more than one occasion I have been allowed by the patient to manipulate the neck under a general anæsthetic, simply because there was, in the patient's mind, the distinct hope that the operation would have a fatal termination. Yet I have never manipulated the cervical spine without earning the gratitude of the patient, and this in spite of the fact that cure has sometimes been impossible, and that I have only been able to secure a degree of alleviation.

It is now a recognised thing among a few medical men to prescribe mobilisation under a general anæsthetic as routine treatment for patients suffering from certain types of pain in the lower part of the back; yet there must be at least as great a number of people who drag on day after day in misery merely for lack of similar treatment for the cervical spine. What is true of the cervical spine is true only in lesser degree of the joints throughout the back.

Rest and Mobilisation.

One of the great difficulties in treating cases of recent injury of the back is to secure adequate rest from strain. In the lumbar region, for instance, complete rest is nearly impossible, except on a plaster bed. It is true that, with the knees drawn up over a pillow, a certain amount of relief can be secured; but if the pillow is a shade too high or a shade too low some element of strain must creep in. All of us are probably aware of the waywardness of a pillow, and the impossibility of maintaining accurate adjustment for any length of time. Moreover, this degree of rest can only be secured while the patient is on his back. Any attempt to lie on the side must inevitably disturb complete rest to some degree

Few of us would expect a synovitis of the knee to clear up with any rapidity if the joint was allowed to exercise the weight-bearing function. Surely, then, it is not surprising when we realise the immense difficulties of preventing lumbar or sacro-iliac joints from bearing weight, that these joints fail to recover rapidly from a similar condition.

It is little wonder that many of these cases of back strain develop adhesions; and, as we know from our experience with other joints, if adhesions are present the correct treatment is by mobilisation. Few of us would imagine that we should be likely to restore a patient whose trouble is due to adhesions in the knee-joint by ionisation, radiant heat, diathermy, massage, or indeed by any treatment other than manipulation. Is it rational to suppose that what it is impossible to effect in the knee-joint we should succeed in performing in one of the joints of the back

The possibility of pain radiating into more distant parts because one of these joints is at fault must be considered. We know, for example, that if a patient comes to us complaining of pain in the knee, and on examination we were unable to discover any sign in the knee itself to account for the symptoms, we promptly examine the hip, and we recognise that pain in the knee is often the first sign of some form of disease of the hip-joint. Why, then, should we fail to realise that pain may be set up in some more distant part as a direct result of a lesion of one of the joints of the spine? Many people now realise the possibility of pain being referred down the leg as a result of a lesion of the sacro-iliac joint, but comparatively few are ready to believe in a traumatic origin—for example, of pleurodynia. Anyone, however, who has experienced the dramatic cure of cases of this type as the result of manipulation must, I think inevitably become a firm believer in the possibility of a locking of a costo-vertebral joint as a cause of most acute symptoms. Yet is it comparatively rare for us to recognise as a cause, shall we say, of brachial neuritis, some corresponding lesion of one of the cervical joints.

I well remember one case which gave me a very useful lesson on the possibility of the occurrence of referred pain as a result of trouble in the upper cervical spine. A young boy had a mild attack of influenza, and for some reason, quite unknown, woke up one morning completely unable to bend his head forwards. On palpation and on manipulation there was definite pain between the third and fourth cervical vertebræ. I was totally unable for a time to account for the fact that there was a considerable amount of pain and discomfort in the neighbourhood of the lower ribs on the same side as the pain was felt in the neck, yet it seemed apparent that the simultaneous origin of the two symptoms must have some common factor. It was only when I remembered the possibility of irritation of the phrenic that I was able to establish the connexion between the two.

Occipital headache, too, is frequently due directly to stiffness in the cervical spine, and can often be relieved almost, if not quite, by manipulation alone. The same may be said of pain throughout the distribution of the branches of the superficial cervical plexus, and we have just witnessed a striking example at this clinic. For over nine months one of our patients had had such severe pain in the side of the face (via the cerviculo-temporal nerve) that she had uninterruptedly worn a thick black velvet shield. Manipulation under ether immediately secured entire relief.

As we descend further down, we may find the pain radiating into the arms. In the thoracic region the nerves of the chest wall may be affected. There is one particular type of this pain to which special attention may be drawn since it is a symptom which earns, for him who can remove it, intense gratitude.

Typical Cases.

Most of us have had women patients who come complaining of pain in the breast, in an agony of fear lest this should be the first sign of cancer. On examination of the breast nothing abnormal is to be discovered, and reassurance is given. When the pain persists, the patient naturally becomes filled with the grave doubts, usually imagining that even if cancer is not already present, the pain must be due to the imminent onset of the disease. Frequently the whole thing can be cleared up in a short time as the result of manipulation.

This circumstance affords an example of the type of case which leaves little cause for wonder that some of the poorly trained and ignorant manipulators claim to be able to cure cancer in the breast as a result of manipulative treatment. The patient believes firmly that this is the only possible cause of the pain; and, when relief follows treatment, both patient and manipulator are readily deceived into thinking that another case of cancer has been cured.

Many unjustifiable claims of having succeeded in curing a patient of indigestion have a similar origin. The low intercostal nerves supply the abdominal wall. Many people, and not perhaps particularly laymen, are liable to attribute pain and tenderness in the epigastric region solely to indigestion. Yet pain will inevitably be felt in this region if there is any condition present at the lumbo-thoracic junction which causes irritation of the twelfth thoracic nerve. The patient, as a rule, has diagnosed his own case as being due to indigestion; only too often this opinion has been backed up by his medical adviser. When no relief is derived from the usual remedies, resource is had to the manipulator; and if, as so often happens, relief is secured, surely both patient and osteopath have some excuse at any rate for claiming that the indigestion was cured by the manipulation. The relief has, of course, followed, not the cure of indigestion, but only the cure of a nerve irritation.

I well know the difficulty of trying the convince a patient who has suffered in this way that I have not succeeded in curing him of indigestion. Personally, I stoutly repudiate the claim, believing that all I have done is to give relief from a pain which the patient has, quite wrongly, attributed to indigestion.

It is doubtless also a similar reason that accounts for the alleged cure of many cases of acute appendicitis by manipulation. We must always remember that McBurney's point is situated half-way down the line drawn from the umbilicus to the anterior superior spine of the ilium. It is seldom recognised that Bear's sacro-iliac point is situated two inches down this line from the umbilicus, and that therefore these two diagnostic points are often separated only by an inch or so. Pain and tenderness in the right iliac fossa is by no means confined to appendicitis. Local tenderness, reflex contraction of the abdominal muscle on pressure, and the posture of the thigh (semi-flexed) are symptoms which may be caused either by a traumatic lesion of the sacro-iliac joint or by appendicitis. In the former condition, however, there is no rise in temperature, little, if any, quickening of the pulse, and, above all, no typical alteration of facial expression; but acute tenderness is felt over the ligaments of the joint when pressure is exerted from behind, a tenderness which is absent in cases of appendicitis.

When we take all these facts into consideration we can readily understand the reason why pain in the right iliac fossa is so often not relieved by removal of the appendix, and we can also, I think, realise that pain in the left iliac fossa need not of necessity be attributed to the ovary.

In this connexion, too, it is only right to refer to the diagnosis so frequently made of lumbago or sciatica. In a clinic such as this, case after case comes to us, week after week, labelled lumbago or sciatica; but here we have grown to regard these names as nearly meaningless. All we infer from the diagnosis is that the patient has pain in the back or leg, and that it is "up to us" to discover the cause. It would be no exaggeration to say, of a hundred consecutive cases sent to us as suffering from sciatica, not more than one or two owe their symptoms to a true sciatica; the remainder are cases of referred sciatica, if indeed the pain involves the distribution of the sciatic nerve at all.

Conclusion.

Let us try to summarise the lesson to be learned by the working of such a clinic as this, with the experience of seven years of uninterrupted work behind us. The first and foremost is, I think, that the medical profession as a whole must review their attitude to the spinal column. It should no longer be regarded merely as the bony home of the spinal cord. We must learn to realise that it consists of bones and joints; that those joints are complicated, and that their mechanism is extremely intricate. Then, too, we must realise that, if these joints exist, they must of necessity be subject to the same ills as are other joints throughout the body, and that they should therefore receive the same scientific consideration and treatment that has been applied to the joints of the extremities. If we recognise and accept the fact that any joint of the extremities can cause symptoms which require manipulation for their relief, we must admit that the same applies to the joints of the spinal column, and no longer withhold from our patients the benefit which manipulation—and manipulation alone—can bestow upon them.

FINGER-PRINTS.

A NEW edition of Sir E. R. Henry's "Classification and Uses of Finger-Prints," which has been issued by H.M. Stationery Office (pp. 142, 3*s.*), brings the total of issues up to six since this useful book was first published in 1900. For those who are engaged in the identification of finger-prints it should be studied in conjunction with the smaller book, "Instructions in the Method of Taking Finger-Prints," also published by H.M. Stationery Office. We learn that on account of its effectiveness, simplicity of working, certainty, and inexpensiveness, the system has now been adopted by practically all civilised States, as is shown by a table of figures compiled at New Scotland Yard. Mr. Charles S. Collins, formerly superintendent of the Finger-Print Branch of the Criminal Record Office, has added an interesting note explaining the method adopted in London. Finger-prints are serviceable not only for identification in criminal cases, but for authentication of certificates of health in the Far East and for the registration of native and Chinese labour. It is now 50 years since Dr. Henry Faulds, who has a good claim to be regarded as the inventor of the finger-print system of investigation, issued a schedule containing outlines of the ten fingers to be filled in with imprints from the palmar pads of each last joint in the serial order of the fingers. These forms were done on copper-plate in Japan, where he was in charge of Tsukiji Hospital, and were circulated freely to explorers, missionaries, ship surgeons, coroners, magistrates, judges, and chief constables. Dr. Faulds's idea was to lay the foundation of a scientific system of personal identification. He intended the records to include soldiers and sailors, in view of the possibility of sudden death and burial without identification, to help in the recovery of lost children, to secure recognition of unknown dead bodies, and of persons who had lost knowledge of their personality by illness. In 1905 Dr. Faulds published a "Guide to Finger-Print Investigation," in which he emphasised his feeling that evidence of this kind can only be kept free from fallacy if submitted to the scientific expert. This guide has long been out of print, and it is Dr. Faulds's earnest wish not to leave the scene before he has been able to issue an expanded and amended edition of the book.

A RECORD OF PHRENOLOGY.[1]

Mr. J. Millott Severn has published privately the story of his life, incorporating his experences as a phrenologist, and it appears fittingly in the centenary year of the demise of Francis Joseph Gall, who is generally accepted as the founder of the cult. The biography gives an interesting description of the life of the author as a child hand on a farm, as a pit-boy, and as a joiner, before the actual experiences of a working phrenologist are reached. These experiences are in many ways quite interesting, while the chapter on the founders of phrenology may be of service to the medical historian. Modern medicine would not, of course, form the same estimate of the importance of phrenology that its followers claim, but there is no doubt that a hundred years ago many medical men believed in the doctrines of Gall and John Gaspar Spurzheim, and that the ideas which they fostered have taken a more scientific aspect with the development of medicine. Those who are sceptical on this point may be referred to early issues of THE LANCET.

MEDIÆVAL WILLS.

ON Dec. 8th, 1784, Samuel Johnson made his last will and testament. A codicil was added next day, in which he left "to Dr. Heberden, Dr. Brocklesby, Dr. Butter, Mr. Cruickshank, the surgeon who attended me, Mr. Holder, my apothecary, and others, each a book at their election, to keep as a token of remembrance." The book that was chosen by Cruickshank was Clarke's edition of Homer. Johnson did not treat his books very kindly, and it is said that Garrick disliked lending him any of his books as they were returned with marginal notes and often in a dog's-eared condition by the great lexicographer. Such marginal notes would add much to the value of any book to-day.

The will of Matthew Hutton, Archbishop of York, made in 1605, contains the following bequest: "Item. I gyve to my ancient good friend, Mr. Christopher Myller, Physician, Paradox Medicorum, set forth by Fuchius." The work in question was by Leonhard Fuchs (1501–1566), and its full title is as follows: "Paradoxorum medicinae libri tres, in quibus sane multa a nemine hactenus prodita, Arabum aetatisque nostrae medicorum errata non tantum indicantur, sed et probatissimorum autorum scriptis firmissimisque rationibus ac argumentis confutantur. Obiter denique hic Sebastiano Montuo medico Rivoriensi respondetur, ejusque annotatiunculae velut omnium frigidissimae procsus explodentur." This work was published in folio in 1535 at Basle. Twenty years later two editions were published in duodecimo at Paris. Copies of the 1555 editions are in the library of the Royal College of Surgeons of England and in that of the Medical Society.

In 1585 Thomas Tobie, of Newcastle, barber-surgeon, made his will. In it occurs the following bequest: "I geve my son George Tobie to my frend Rauffe Tate, with the booke of Marters, the Erball, Johannis de Vigo, Bullin's booke, with a metall pott and a bason." Of these books, the marters is John Fox's "Acts and Monuments of these Latter and Perillous Days," &c. (London, First edition, 1562); the Erball is possibly William Turner's Herbal, printed at Cologne in 1568, in folio; John of Vigo's "Works of Chirurgerye," was translated by Bartholomew Traheron, London, 1543, in folio; while Bullin's booke is either William Bullein's "Government of Healthe," London, 1558, or his "Bulwarke of Defence against all Sickness, Sornes and Woundes that dooe daily assaulte Mankinde," London, 1562. Another barber-surgeon, of Newcastle, George Fuister by name, made his will in 1592 and among other bequests left, "to my nurse, 2*s.* 6*d.*"

Few save those who have studied the matter can form any idea of the interest, and, indeed, the amusement, that can be derived from a perusal of a mediæval will. These wills were religious documents and were proved in the ecclesiastical courts. In pre-Conquest days wills were made verbally and if reduced later to writing were of a noncupative character; but by the twelfth century it had become usual to record the will in writing, and this was essential if there was any question of a legacy of land, though people were left free to make a verbal disposition of their chattels, if they so desired, until comparatively recent times.

In mediæval times the parish priest had to be present to hear the confession, usually spoken of as the last words, or "novissima verba." From the eleventh to the thirteenth century there was a horror of intestacy amounting to positive dread; it being held that a man dying intestate died unconfessed, and was therefore unfit for burial in consecrated ground. So great was this horror that the stock phrase, "nolens decedere intestatus" is constantly cropping up in the opening sentences of many wills of the period. Another stock phrase, "quia nichil certius morte, nichil incertius hora mortis," which we owe to Bracton, obviously alludes to the uncertainty of life. In the register of John de Peckham, Archbishop of Canterbury, 1279–92, will be found an account of a man who was attacked by robbers and was found by neighbours at death's door; he died before a priest could be brought to him and was buried in the high road. Peckham took a merciful view of the case: "It is said that the poor wretch asked for a priest, if this can be proved, let his body be exhumed and buried in Christian fashion, for he did what he could towards making a testament." This would seem to have been the beginning of an attempt by men to discriminate between the case of a man dying suddenly by accident or disease, "subita et inpreparata morte," and the person, who, lying sick, obstinately refused to utter his last words, and died "desperate" as the saying was.

At this early date it was considered unlucky to make a will when in good health, and in most cases a very short time elapses between the signing of a will and its probation, rarely more than a few weeks elapse and occasionally only a few days. In times of epidemics, such as the plague, men were evidently influenced by fear of imminent peril. In this respect Canon Foster, in his introduction to the magnificent collection of Lincoln wills (Lincoln Record Society, Lincoln Wills, vol. ii., 1918), to which we are much indebted for most of our knowledge of the subject, instances the following: "Of a hole mynde and perfyte remembraunce, preventyng by the grace of God the incerten stroke of dethe and the sodan knockyng and flagicion of Allmighty God, now beyinge in good helthe makyth my last will and mynde."

After having commented on the uncertainty of life the mediæval testator proceeds to leave his soul to the Almighty and his body to the earth whence it came. The church is almost always mentioned and much money is usually directed to be spent by his executors, that to be spent on wax for candles being usually specified. Before making any other bequests he mentions his mortuary, called in old wills the "principalium." This mortuary, or soul-scot, was a sort of religious heriot allowed by custom to the priest of the testator's parish; it usually took the shape of his best beast or best garment. Selden says that the mortuary was for tithes forgotten, a sort of death bed restitution, like conscience money to the Chancellor of the Exchequer; though this may have been so in some cases, one can find in any collection of old wills numerous examples of money left to the altar of the church for tithes forgotten as well as the mortuary. When we get to the body of the will we find the most entertaining bequests of the goods of the departed, and the reader is often set a pretty puzzle to understand what some of the articles were.

In reference to the dread of dying without making a will, the saying may be recalled of one of the old monkish chroniclers (? Symeon, of Durham), who in recording the death of some man, says that he died in the night and was found by his servants next morning, dead, black, stinking, and intestate!

THE MELANCHOLIA OF SEMMELWEIS.

IN his Semmelweis Cup speech delivered at the annual conference of the Budapest Medical Club Prof. Rezső Bálint discussed the causes of Semmelweis's melancholia which, as is well known, led to his admission to an asylum in 1865 at the age of 47. We often read, he said, even in modern medical literature, that Semmelweis suffered acute distress of mind owing to lack of understanding or misjudgment of his doctrines on the part of his contemporaries, and that throughout his life he felt himself to be persecuted by an inexorable fate. But Semmelweis was not the only man who had to bear this misfortune; many a man of genius, who has sought to divert or accelerate the ordered progress of culture by some unexpected act or discovery, has shared his fate. It has happened not uncommonly in the history of science and the arts that a few individuals of commanding genius have risen high above the level of their contemporaries, and that many years have passed before a later generation has attained the horizon of their outlook, and learned to understand and appreciate them. Brandes says in his book on Goethe that the cultural development of a period, or of a nation, can be measured by the degree of comprehension it shows for the spirit of Goethe—as Auerbach puts it, how "Goethe-ripe" it is.

But the failure to understand and recognise the value of Semmelweis's work was a far more serious matter than the inability to appreciate Goethe's poetry. If a man is unable to enjoy Goethe his loss is spiritual only, but the failure of contemporary scientists to comprehend Semmelweis's theory, and their refusal to put it to a practical test, sacrificed the lives of thousands. And yet how simple was the truth which he proclaimed, how much more difficult and confused the lines of thought on which his opponents sought for a solution of the problem—the discovery of the cause of puerperal fever. Telluric, atmospheric, cosmic changes, psychic influences, and other factors difficult of analysis distracted their minds, and the simple truth which flashed upon Semmelweis in all its splendour when he compared the death-rates of the two sections of the Viennese Obstetrical Clinic made no appeal to them. The very fact that the doctrines found access with difficulty to the minds of his contemporaries is proof of their magnificence. What freedom from prejudice, from bondage to accepted doctrines, what intellectual daring it required to recognise so revolutionary a truth and champion it with zeal against all assailants! In his open letter to Spaeth, Semmelweis wrote: "You also take part in this slaughter, Professor! But the killing of women wholesale must be stopped, and I myself will stand sentinel. Anyone daring to proclaim dangerous doctrines about puerperal fever will find in me a doughty opponent." The fact that his theory was not recognised caused him pain, not from vanity, but because he knew that its non-acceptance was costing many a mother her life. This painful consciousness perturbed and depressed him, but could not diminish the happiness of the knowledge that a new truth, to which thousands would owe their lives, had originated in his brain.

It cannot be true, said Prof. Bálint, that great souls are made unhappy by the failure of the world to understand them. Man may strive in all his thoughts and acts to attain contentment, but true happiness is experienced only by those who find it in themselves.

> Erquickung hast du nicht gewonnen,
> Wenn sie dir nicht aus eigner Seele quillt.

Are we justified in assuming, from the sullenness of Beethoven's face, from the gloomy utterances in which he indulged, that this great soul was unhappy? Does not the Ninth Symphony resound with joy? Is there one of his works that is not dominated by gaiety? Surely Beethoven could not have composed music that was not a reflection of his own feelings. Great souls like these, confronted with human ill-will or uncomprehension, find these but trifling vexations in comparison with the supreme contentment that dominates their souls. Can we imagine that Semmelweis would have sacrificed this great truth to win the applause of his contemporaries?

VITAMIN C IN LIVER.

THE use of liver and liver extracts in the treatment of pernicious anæmia has led to the study of these substances as a therapeutic agent in other disorders. In the nutritional diseases of infancy and childhood some observers claim excellent results with various forms of liver diet. That liver contains fat-soluble vitamin is, of course, well known, but a certain amount of research has also been undertaken upon its antiscorbutic value, dependent on the presence of vitamin C. H. Aron, H. Hirsch-Kauffmann, and E. Schädrich[1] have conducted experiments on guinea-pigs, using as a control basis a scurvy-producing diet consisting of 20 g. of sterilised oats and 30 g. of sterilised milk daily. In three animals this produced in about three weeks typical scorbutic collections of blood in the neighbourhood of the ends of the long bones and these changes could be demonstrated by the X rays. In a fourth animal a portion of the oats was replaced by pulped liver so that the protein intake was the same as in the control animals. This form of liver was, however, not relished by the animal and failed to prevent the appearance of scurvy. Consequently it was decided to employ a water extract of fresh liver and this was prepared by pounding 60 g. of liver pulp with 60 c.cm of water in a mortar and allowing it to stand in an ice-chest for 24 hours. The mixture was then filtered and a somewhat cloudy, bright red filtrate obtained.

About 5 to 6 c.cm. of this liver juice appeared to be equivalent to 7·5 g. of fresh ox liver, and daily administration of this amount of liver prevented scurvy in guinea-pigs fed on the scorbutic diet mentioned above. On testing the thermostability of the liver extract it was found that heating for five minutes in a boiling water-bath considerably altered its colour and consistency, but left its antiscorbutic power unaffected. Alcoholic extracts of fresh liver, the residue of these extraction processes, and a preparation called "hepatrat" were found to have no antiscorbutic power such as the simple water extract had shown.

These studies are interesting as indicating how the vitamin C content of liver may best be obtained for therapeutic purposes. So far as infantile scurvy is concerned a new antiscorbutic preparation is hardly wanted, since cases can readily be cured with fresh fruit juice, unboiled milk, and such substances as "potato cream." It is possible, however, that some infants would tolerate a water extract of liver better than fruit juice as a prophylactic agent.

THE GUARDIANSHIP SOCIETY.

THE work of the Guardianship Society, which has its headquarters at Brighton, was described in the sixteenth annual report presented on March 23rd. The object of the Society is the care and supervision of the mentally and physically defective, and other special cases, and during 1928 no fewer than 876 persons were under care, while another 70 cases had been visited voluntarily in their homes and otherwise helped, bringing the total number of persons assisted or supervised to 946. This figure does not include after-care patients, in which category there were 225 on the register at the end of the year, *an increase of* 88 in the 12 months. The persons under care may be classified as follows:—

Certified under Mental Deficiency Act	425
In a "*place of safety*"	3
Notified under Section 51	90
Under single care under the Lunacy Act	9
Physical defectives and others boarded-out	260
Under statutory supervision in their own homes ..	89
Total	876

The Society's clinic for nervous disorders has been open now for three years, and 48 sessions were held in 1928, 102 patients (45 male, 57 female) being treated. The Society has two homes in the country—at Dungates, and Jarvis Brook, Sussex—and at the latter place another home has been started where backward boys, and a certain number of lads on licence, are trained in gardening, and rabbit and pig breeding. There are two industrial class centres—one in Brighton and one in Hove—and there is also a special school for defective children in Hove. Interest and financial help is urgently needed for the furtherance of this work among the mentally and physically defective. At the annual meeting a high tribute was paid to the work of the hon. secretary, Miss Grace Woodhead, under whose guidance the administrative expenses are only 3¼ per cent.

Dr. Crichton Miller addressed the meeting on the Duty *of Society towards the Subnormal Child. He pointed out* that instead of the ordinary problem of educating the individual so that he might adjust himself to his environment the Society were faced with that of devising an environment suited to the individual.

THE PANEL SYSTEM IN BIG TOWNS.

To the Editor of THE LANCET.

SIR,—With regard to the letter of "Aggrieved" in your issue of Feb. 23rd (p. 420) which has just been brought to my notice, I feel that, both as a panel practitioner and one of those requested to attend by "Aggrieved," I should like to answer. The charge against the panel practitioner is that he "may reap the fees while other doctors do the work." This is due to a misconception on the part of "Aggrieved." No medical man reaps fees on account of maids who are on no one's panel list. "Aggrieved" does not realise that insurance work is contract work. One agrees to attend at all times patients on one's panel, and other insured patients in emergency, whether on one's panel or not. There was no obligation to attend "Aggrieved's" maid on either of these counts. A case of influenza in the house of a doctor is scarcely an emergency.

In addition, I should like to remind "Aggrieved" that the request from an employer to take his maids on to one's panel, with the proviso that he would pay for the first visit as a private one, is always insulting, and doubly so in the case of one doctor to another. As regards difficulty in getting drugs dispensed at certain hours, this of course exists, and is usually well met by giving domestic remedies. Were no aperients, no aspirin present in "Aggrieved's" own house?

I am, Sir, yours faithfully,
PANEL PRACTITIONER.

Pimlico-road, S.W., March 28th, 1929.

THE PUBLIC SCHOOLS YEAR BOOK.

THIS year book, which is the official book of reference of the Headmasters' Conference, now appears for the fortieth time (London: H. F. W. Deane and Sons. Price 10*s.* 6*d.*) It contains a list of the public secondary schools represented on the Conference and the Editors have spared no efforts in making the information accurate and complete. Parents will be interested in the sections dealing with the entry to the services, professions, and various business careers. Scholarships given in aid of medical study are set out at length in a table of 26 pages in a most serviceable way. There is an alphabetical list of old and new works of reference concerning schools and colleges or their historical memorials, lives of headmasters, school registers, magazines, and so forth. For instance, the reader is referred to "Our Schools and Colleges" by Captain Frederick Shirley de Carteret-Bisson, the fourth edition of which was published in January, 1879. This book, now out of print, was a veritable mine of educational information in *the seventies. Details of public* schools outside the Headmasters' Conference are not included in the year book, the conditions under which a school may be represented being briefly stated in the preface. Parents, schoolmasters, and boys will all find interesting information and records in the book.

"TRANSPULMIN" IN TUBERCULOSIS.

Harlan F. Newton and Kurt Heine[1] report beneficial results from the intramuscular injection of transpulmin. This is a sterile solution of basic quinine and camphor in ether oils. Quinine accumulates in the lungs and together with the ether oils is said to exert an antisecretory effect upon the mucous membranes of the lung tubes. The success attending the use of transpulmin in chronic bronchitis, pulmonary abscess, and bronchiectasis led the authors to try its effect on 40 cases of pulmonary tuberculosis. The selected cases were of the productive and cirrhotic types, acute infections and those of the cavernous type being excluded as unsuitable. Treatment was continued daily for three to five weeks. Favourable effects were noted in 28 patients, cough was relieved, fever diminished, expectoration reduced, and tubercle bacilli banished from the sputum in all but two of the cases. No ill-effects were noted, while decrease in physical signs and improvement in the X ray picture resulted.

Goulstonian Lectures

ON

POLYURIA

Delivered before the Royal College of Physicians of London

By ERNEST BASIL VERNEY, M.B. Camb.,
F.R.C.P. Lond.,
PROFESSOR OF PHARMACOLOGY IN THE UNIVERSITY OF LONDON, UNIVERSITY COLLEGE.

Lecture III.*—POLYURIA IN CHRONIC NEPHRITIS.

(Delivered on March 14th.)

Mr. President and Fellows,—In the first lecture emphasis was laid on the dependence of the kidney for its physiological conduct, in so far as its rapid and purposive response to an increased load of water in the tissues is concerned, on the secretory activity of the pituitary body. Such dependence may—we do not know—represent one aspect only of a fuller reliance by the kidney on the metabolic activities of the endocrine glands. But this much is clear—viz., that the water elimination by the normal kidney is profoundly influenced by the content of the blood in the secretory product of the pituitary gland. And, in that both when the secretion of the pituitary body is impaired by experimental interference and by the incursions of disease, the physiological background of the kidney must itself be sufficiently reactive in order that the typical response to the lowering of the pituitrin content of the blood may be made manifest, it is not surprising that there is close agreement between the findings of pathology and those of experimental physiology.

The interpretation of the polyuria which is seen to accompany certain forms of chronic nephritis seems in the present state of knowledge to be a much more difficult problem, and one feels acutely that anything one has to say on the subject is necessarily disjointed and speculative. But it may not be entirely without value if the clinical and pathological facts, as generally accepted at the present time, are first described, and then, in the light of our present knowledge of the physiology of the kidney and of the cardiovascular system, an attempt made to form some conception of the mechanisms responsible for the exhibition of these facts.

Polyuria is typically associated with those structural changes which are found in the so-called contracted white kidney. The glomeruli are extensively and unequally damaged, and show varying degrees of patency in the capillary loops. The tubules exhibit marked signs of degenerative changes, these changes being perhaps dependent on the degree of glomerular damage (Löhlein [8]). The structure of the kidney is extensively altered, depending partly on the destruction of the specific parenchyma, partly on regenerative processes. Polyuria, especially nocturnal polyuria, is often the first symptom of the disease, but "no close parallelism exists between the weight of the kidney, its appearance, and the amount of urine it secreted before death" (Osler [11]). And all attempts to correlate the degrees of structural change with the functional responses of such kidneys fail. But when the structural changes are intense the polyuria may be said to be obligatory, and raised arterial tension is persistent and extreme. The vasculature of the kidney shows extensive arteriosclerotic changes, but that these changes are secondary to the raised arterial tension is made unlikely by the fact that they may be strictly localised to the kidney or be at least much more extreme in their degree here than elsewhere in the body. The presence of such localised vascular changes in the kidney, associated as they are with high blood pressure, is an argument, as Volhard and Fahr [20] point out, in favour of their being connected as cause and effect. As already mentioned, nocturnal polyuria may be the first symptom of any derangement of renal function, and this may occur in the absence of any sign of a rise in the general blood pressure. On the other hand, high blood pressure is not necessarily associated with polyuria, as is well recognised in the fact that generalised arteriosclerosis, raised arterial tension, and cardiac hypertrophy are commonly encountered without there being any signs or symptoms of impairment in the function of the kidney. In such conditions the amount and colour of the urine may remain normal for many years, and the marked oscillations in the rate of urinary flow during the day, a phenomenon which above all others is to be regarded as a sign of normality in renal function, are as a rule conspicuously present. Quincke's [14] nycturia, it is true, is a symptom which is sometimes evident, but it is by no means invariably so. Tests of renal function, such as the water ingestion test, concentration tests involving the capacity of the kidney to excrete chloride or urea, give results which are commonly within the normal range—facts which are clearly to be associated with the retention of comparatively large amounts of normal renal tissue and with the frequency with which zones of hypertrophied parenchyma are met with. Such cases die not from renal insufficiency, but from causes due immediately to the structural or functional state of the cardiovascular system, whilst those afflicted with the diffuse chronic nephritis with which we are here mainly concerned die in latent or acute uræmia, or are prematurely carried off through the rupture of a cerebral blood-vessel. One pictures the "contracted white kidney" as arising from the continuous action on the kidney of some toxin locally or remotely produced, the "primary contracted kidney" as arising directly from a generalised vascular disease. Forms of kidney disease intermediate between these two main types may be encountered, but I think it would be generally agreed that in their purest forms these two types do exist and that clinically they may be readily recognised and differentiated.

The colour of the urine in the polyuria of chronic nephritis is pale, its specific gravity is low, ranging from 1005 to 1012, and the amount of albumin is variable, sometimes being hardly detectable, at other times abundant. Traces of blood are commonly present. The earliest functional change which can be detected in this progressive disease is the damping down of the normal variations in urinary output during the day. Hedinger and Schlayer [6] introduced a method of testing renal function which was based on this fact. The volume, specific gravity, and chloride content of the urine collected at two-hourly intervals during the day, and of that collected during the whole night, were measured. It was found that whereas in normal people there were wide variations in the figures relating to the specimens collected during the day, in chronic nephritis without œdema the curves showed a marked constancy in level throughout. The volume of urine was larger and such variations in the rate of urine flow as did occur were not reflected in any marked change in specific gravity or chloride content. In more severe cases there is an increase in the volume of the night urine, and when this occurs Hedinger and Schlayer state that there is widespread damage to the kidney parenchyma. But no definite relationship exists between the degree of structural damage to the kidney and its functional response. Mösenthal [10] repeated and extended the observations of Hedinger and Schlayer and made comparative tests of the effects of high and low protein diets in various forms of renal disease. It was found that nocturnal polyuria was much more frequent on the high than on the low diet, and it was concluded that when this symptom occurred with a low protein diet it was to be regarded as a much graver sign of renal insufficiency than when it occurred with a high. The nocturnal polyuria, as Volhard and Fahr [20] conclude, is to be regarded as a compensatory phenomenon.

---

* Lectures I. and II. appeared in The Lancet of March 16th and 30th respectively.

When the capacity of the kidney to concentrate some specific substance such as urea or chloride is investigated it is found that such capacity is markedly diminished in severe or protracted forms of the disease, but that in the earlier stages, even when nocturnal polyuria is present, the capacity to deal with these substances may be to all intents and purposes normal. Tests involving the ingestion of a large volume of water and timing its rate of elimination may show a delayed excretion rate at a stage before that at which any marked impairment in the capacity of the kidney to eliminate urea is encountered. Later the incapacity to excrete large volumes of water rapidly ingested is very marked, and the immediate effect may be an actual diminution in the rate of water elimination (Mösenthal [10]). This incapacity to deal with large additional volumes of water is probably not unrelated to the fact that the polyuria of this disease does not respond to the administration of pituitrin (Hart [5c]). In this respect, then, it differs sharply from the polyuria of diabetes insipidus.

Blood analyses show an increase in the urea and in the non-urea non-protein nitrogen, and the value of these findings in forming an estimate of the degree of renal damage is very appreciable. The retention of other substances such as potassium, phosphate and creatinin in the blood of cases of chronic nephritis has also been reported, and reference will later be made to the significance of this retention. The disease may arise as a sequel to chronic parenchymatous nephritis, but quite commonly there is no history of dropsy, and the polyuria may, and quite commonly is, the first symptom of impaired renal function.

We may, then, sum up the clinical and pathological picture of chronic nephritis with polyuria as follows. In the earliest stage of the disease the first sign to be detected is a disappearance of those rapid swings in the rate of urine eliminated during the daytime which characterise health. Such a disappearance is accompanied or quickly followed by an increase in the volume of urine eliminated during the night. The quality of the urine tends towards a fixed and constantly maintained level in so far as its chloride content and specific gravity are concerned. Albumin is, and blood may be present. Water excretion, urea concentration, and chloride concentration tests, as well as the concentration of urea in the blood, may show little variation from the normal, and no rise in blood pressure may be detected.

As the disease progresses the polyuria becomes more marked, and tests for renal efficiency show that the capacity of the kidney to deal with a suddenly imposed load is waning. The amount of albumin and of blood in the urine is variable, and the urea content of the blood slowly goes up. The blood pressure rises and the rise is persistent. Later these signs and symptoms become more severe and death usually ensues from renal failure.

Our task, then, is to attempt to interpret in terms of physiological mechanisms with which we are already familiar, the signs of this disease and the course which it typically follows. The points which must particularly attract our attention are, in addition to the polyuria, the occasional absence of a raised blood pressure in the early stages, the marked and persistent rise which occurs in the later, the presence of albumin and blood in the urine, and the ingravescent fall in the capacity of the kidney to deal with any extra load to which it is subjected. Further, we must attempt to account for the absence of an increased urine flow in cases of essential hypertension and of generalised arteriosclerosis with high blood pressure.

Let us now turn to a consideration of those facts in the experimental physiology and pathology of urine secretion and of the cardiovascular system, which, so far as our present knowledge goes, may be considered to have an important bearing on the mechanisms behind the production of the polyuria and the course of the disease of which it forms so prominent a sign.

The first fact which I should like to emphasise is the enormous number of renal units which are packed together to form the human kidney. If we make a section tangential to the surface of the kidney we find that the medullary rays are represented as circular areas, the labyrinth of the kidney as the tissue intervening between them. If we examine such a section microscopically we find the medullary rays to be formed by the collecting tubules, whilst in the labyrinth immediately in contact with the medullary ray is a zone of convoluted tubules surrounded by a zone of glomeruli. Masses of such lobules are packed together to form the whole cortex. These lobules have been found to be structurally separable by Traut.[18] After maceration of pieces of human kidney tissue in 50 per cent. HCl for 8 to 12 hours he found that the lobules readily fell apart and that their structure could easily be investigated. The whole cortical surface of the lobule was clustered with glomeruli, inside which were packed the convoluted tubules which themselves formed a compact sheath around the cortical collecting ducts. It was possible to determine the number of these lobules in the human kidney, and by counting the number of glomeruli on the surface of several such units the approximate number of glomeruli in the whole kidney became known. This number is $4{\cdot}5 \times 10^6$, so that the normal man is provided with roughly 10 million units each potentially capable of supplying its quota of fully formed urine. That such an enormous number represents a considerable reserve of secretory tissue is indicated by the results of the experiments of Richards [15] and his colleagues.

Richards has shown by direct observation of the glomerular tufts of the frog's kidney that the number of active glomeruli—i.e., those through which a flow of blood is visible—varies continuously, and that the number of active glomeruli in a given field can be increased by injections of diuretic substances and diminished by injections of vasoconstrictor substances. Further, Richards has demonstrated the possibility, under the microscope, of puncturing the capsule of a glomerulus with a fine quartz pipette and of withdrawing by this means fluid from Bowman's space. The fluid flowed up the pipette only so long as blood was observed to pass through the glomerular capillaries. If these were touched with the point of the pipette they contracted down and the flow of fluid ceased. It would seem, then, that the secretory work of a renal unit was dependent on the flow of blood through its glomerulus.

Two results accruing from these experiments are of special interest to us at this juncture—namely, the alternation in the flow of blood through the glomerular tufts, and the cessation of the flow of fluid collected from Bowman's capsule when the blood flow through that glomerulus ceases. Each unit passes through alternate periods of rest and activity, and as we should perhaps expect, these interruptions are not regular in occurrence and do not affect all the glomeruli within a single field at the same time. The number of units is so large that it is possible for the kidney as a whole to function efficiently under normal conditions when each unit composing it works for a fraction only of its time. Such experiments give us a clearer insight into the meaning of the term "reserve of the kidney," since clearly, when increased work is called for, the units simply respond either by increasing their intervals of work at the expense of their intervals of repose, or by increasing the intensity of their work during their active periods. This alternation of activity and rest which the units of the kidney undergo may be looked upon as the concrete representation of its first line of defence against the inroads of disease.

We have already emphasised the dependence of the urine flow on the pressure stimulus. It does not necessarily follow that a rise in general blood pressure causes an increase in urine flow. Stimulation of the splanchnic nerve, for example, inhibits or arrests the flow of urine since the vasa afferentia are constricted and the pressure stimulus withheld from the glomeruli. The seat at which the pressure stimulus becomes effective—viz., the glomerulus—being situated between the vasa afferentia and the vasa efferentia can, by means of a differential dilatation or constriction of these vessels, become exposed theoretically to any blood pressure from zero up to a value approximating to that of the general arterial pressure. This possibility of an enormous variation in glomerular pressure gives to the kidney its second intrinsic line of defence. But whereas in the calling up of its first reserves the composition and quantity of the urine would not necessarily be altered, *immediately the second reserves are called into* play an increased urine flow occurs accompanied by an approach in its composition towards that of the plasma. The degree of this approach is to be regarded as being determined by the "tone" of the individual units just as the degree of dilatation of the heart when subjected to an increased load is dependent upon the efficiency with which the extra work is performed. We saw in the last lecture two illustrations of this mobilisation of the second reserves of the kidney. In Rose Bradford's experiments a polyuria supervened, the degree of the polyuria in the non-fatal cases being roughly proportional to the amount of kidney substance removed.

Attempts to prove the results obtained by Rose Bradford [4] in his experiments on the reduction of the renal tissue have been undertaken by Bainbridge and Beddard,[2] and by Pearce.[15] Bainbridge and Beddard applied Bradford's technique to three cats. With *regard to the effects of such operations on the amount* and concentration of the urine they make the following observations:—

> "Making allowance for variations of diet, we find no evidence that the amount and specific gravity of the urine are necessarily modified by either the first or second operation. Only one cat almost invariably passed abundant quantities of dilute urine after the first operation, the others often passed a concentrated urine. . . . It may be *concluded, therefore, that the increase in quantity and* decrease in concentration of dog's urine after operations on the kidneys is an incidental rather than an essential *result.*"

But even the incidental disclosure of a mechanism may detract in no measure from the importance of the recognition of such mechanism in attempts to interpret the polyuria resulting from disease. In Pearce's experiments which were made on dogs no comments were *made on the volume of the urine, since the* experiments were designed to check Rose Bradford's observations on the influence of the kidney on nitrogenous metabolism. In the two experiments, however, in which it is possible to compare the outputs of water before and after the reduction in renal substance, it is significant that water additional to the usual allowance was given in the post-operative period, and this increased intake was reflected in an increased output of urine and by a fall in its specific gravity. Pilcher [13] ligated successively the branches of the renal arteries in one cat and one dog and did not observe any change in the output of water. Hermann,[7] on the other hand, recorded an increase in the few of his experiments to which reference was made in the last lecture. The acute effects of ligation of part of the arterial supply to the denervated kidney of the intact dog have, as far as I have been able to determine, not yet been fully investigated. It would appear, then, that an increased output of water following the experimental reduction in the amount of functioning tissue is not invariable in the intact animal. But the important point to realise in so far as the pathology of urinary secretion is concerned, would appear to be the fact of the possible occurrence of such polyuria. Disease may discover mechanisms in the cell which, under experimental conditions, are only brought to light by some peculiar combination of circumstances.

In the experiments on the isolated kidney we saw how the functional removal of approximately half the kidney was followed immediately by an increased flow of urine from the part which was still perfused, an increased flow, moreover, which possessed all the attributes of a pressure diuresis. And we suggested, without being committed to the exact mechanism involved, that each part of the kidney was normally exerting an inhibitory influence over the remainder. Further, it was shown that the functioning part of the kidney was now more susceptible to an externally applied stimulus in the form of a rise in the perfusion pressure. In the whole animal, therefore, it would not be surprising to find that when this second reserve of the kidney was exhausted and all the renal units were *receiving the maximum stimulus which under* the circumstances could be given them, and yet were unable to cope with the work thrust upon them, there should be a call for external aid in the form of a rise in the general blood pressure.

We must now discuss the means whereby this can be brought about. In 1889 Rose Bradford [5] undertook an investigation into the innervation of the renal blood-vessels, determining amongst other things the origin and course of the vasoconstrictor fibres and the existence and course of the vasodilator fibres. The effects on the kidney volume and on the blood pressure of stimulating the dorsal and lumbar nerves seriatim were investigated. It was found that "stimulation of the anterior roots or of the entire nerve after division of the posterior root" . . . was "followed by contraction of the kidney and a rise of general blood pressure when any nerve from the sixth dorsal to the second lumbar inclusive was the one selected." Although *the excitation of all these nerves produced contraction* of the kidney and a rise in blood pressure, yet on the whole stimulation of the lower nerves was more efficacious than stimulation of the upper, the greatest contraction of the kidney being caused by stimulation of the eleventh, twelfth, and thirteenth dorsal nerves. Thus the area from which the kidney vessels are supplied is a very extensive one, and, as was pointed out, it was apparently coextensive with that supplying the abdominal vessels. It was now found that when such a nerve as the thirteenth dorsal, which with quick rates of stimulation always gave a renal contraction and a rise of general blood pressure, was excited by means of slow rhythmic break shocks of one per second or even one every two seconds, the kidney underwent marked expansion and no change in blood pressure occurred. "Just as the quick rate of excitation invariably produced contraction of the kidney, so the slow rate produced expansion." "This *renal expansion had a short latent period and the* rate of expansion was slow, considerably slower than the rate of contraction for the same nerve. Like the contraction effect, however, the expansion was of a persistent character, and generally the kidney remained for a variable time more expanded than it was previously to the stimulation." This true active dilatation of the kidney was only to be obtained by the stimulation of such a comparatively restricted series of nerves as the eleventh, twelfth, and thirteenth dorsal, the same series as that for which the most marked renal vasoconstriction was observed when high rates of stimulation were employed. The presence of these dilator fibres was demonstrated in the splanchnic nerves, and no evidence was obtained which militated against the view that the renal vasodilator nerves reached the kidney by the same path as that followed by the renal vasoconstrictor nerves.

So far, then, the existence of efferent vasodilator as well as vasoconstrictor nerves to the kidney had been clearly demonstrated, the nerves leaving the cord in the anterior roots of the lower thoracic nerves, passing thence to the splanchnic and so to the renal plexus. The reflex phenomena of the renal vessels were next investigated, and it was shown that by reflex excitation, be it from the central end of the sciatic or from the central end of an intercostal nerve, it was more common to obtain contraction than expansion of the kidney, but that expansion was frequently obtained by the excitation of a posterior root of a nerve belonging to what may be called the renal area—i.e., eleventh, twelfth, and thirteenth thoracic. I will, if I may, quote from one of Rose Bradford's papers (51):—

> "If a posterior root below the third lumbar nerve be excited, the rise of blood pressure is similar to that seen

on excitation of the great sciatic; if, however, the central end of one of the upper lumbar or lower dorsal posterior roots be excited the rise of blood pressure is far greater in amount and more sudden in its onset; in fact, the effect is quite different to that seen with the lower roots. The anterior roots of these nerves contain, as we have seen, the vasoconstrictor fibres distributed to the vessels of the viscera, and these observations tend to show that these posterior roots also contain special afferent fibres capable of affecting the vasomotor system to a far greater extent than the ordinary afferent fibres seen in sensory nerves. In other words, this great and sudden effect on the blood pressure would tend to show that some posterior roots contain afferent fibres derived probably from the viscera and from the kidney, amongst other viscera. The fact that there are such nerves distributed to the kidney and that the excitation of their central ends is capable of causing a very great effect on the vessels of the body generally, is also a fact that may have some bearing on the production of high tension in certain renal diseases. The other point of interest about these afferent visceral fibres is that, although their excitation causes a rise of blood pressure with general constriction, there is a local dilatation of the kidney—in fact, this is the only method by which, experimentally, any very considerable dilatation of the renal blood-vessels can be produced."

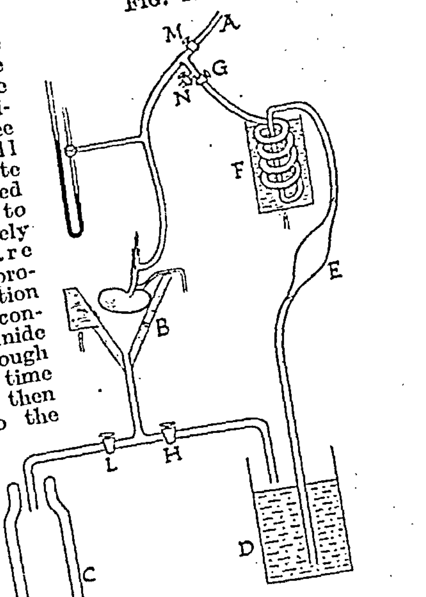
Stimulation, then, of the afferent visceral nerves in the renal area will lead to a reflex active dilatation of the renal vessels and reflex constriction of the vessels of other viscera, occasioning a rise in the general blood pressure.

In the normal animal, however, any rise in general blood pressure is quickly compensated by the bringing into play of the depressor mechanism. A rise in cerebral blood pressure leads, as the cross circulation experiments of Anrep and Starling[1] have clearly shown, to depression of the vasomotor centre and dilatation of the vessels in the splanchnic area. This maintenance of constancy in the arterial blood pressure is one of the most remarkable of physiological facts, any increase in the blood-supply to a particular organ or part of the body being instituted by a redistribution of blood at constant blood pressure. In the normal animal, therefore, the mechanism for causing an increase in the blood flow through the kidney at a constant mean arterial blood pressure is present, and if such reflex dilatation of the renal vessels were exerted to a greater extent on the vasa afferentia of the kidney than on the vasa efferentia an increased glomerular pressure would result. A *sustained* increase in the general arterial pressure could theoretically be initiated in one or more of three ways: firstly, by a general diminution in the capacity of the cardiovascular system produced, for example, by the presence in the blood stream of a substance which caused and maintained an increased degree of contraction of the smaller blood-vessels; secondly, by the continuous stimulation of afferent visceral nerves passing to the vasomotor centre, thus maintaining it in a continued state of increased tone; and, thirdly, by the action of some substance of a chemical nature directly on the vasomotor centre, setting it, so to speak, at a higher tonic register, just as the fever toxins set the thermoregulatory centre to work at a higher body temperature. The mechanism of the production of high blood pressure in man is quite unknown, but in the light of our physiological knowledge of the vital importance of the vasomotor centre in maintaining and controlling the level of the arterial blood pressure in the normal animal, and of our pharmacological knowledge of the manner in which this centre can be influenced by the presence of drugs in the blood stream, it would seem irrational to adopt in explanation of this condition any theory which failed to involve the vasomotor centre as a causative factor in its production. In the high tension found in kidney disease, therefore, our physiological knowledge would predispose us to the view that its original cause was to be found either in a reflex, initiated in the kidney, to the vasomotor centre, or in the circulation of some abnormal substance, or normal substance present in abnormal amount, which had a sustained influence on this centre. In this connexion it would seem advisable to bear in mind the possibility of the vasomotor centre's permanently retaining a functional state originally impressed upon it by nervous or chemical agencies which later cease to function or disappear.

It need scarcely be remarked that mere diminution in the blood flow through the kidney, considered purely as causing mechanically an increase in the peripheral resistance of the vascular system, cannot be entertained as a primary factor in the production of the high tension with which we are concerned.

We must now pass to a brief consideration of the effects of anæmia on the kidney. Temporary asphyxia of the kidney by occlusion of the renal artery was shown by Marshall and Crane[2] to produce on release of the vessel a urine which approached in its percentage composition the blood plasma. Moreover, the urine contained protein, but this quickly disappeared and the composition of the urine soon returned to its state before the artery was occluded. Similar effects can be shown to be produced in the heart-lung-kidney preparation. In the experiment to which I am referring, after obtaining a number of samples of urine from the surviving kidney the artificial respiration was stopped. The heart continued to beat and to maintain a blood pressure of 110 mm. Hg, while the blood in circulation gradually became darker as the heart and kidney used up the oxygen. Towards the end of the asphyxial period and up to the time that the heart failed there was a steady rise of chloride in the urine—i.e., the urine approached in composition the protein-free blood plasma. Still better and more definite results were obtained by the use of cyanide to inhibit or completely eliminate the share taken by oxidative processes in the formation of the urine. Blood containing a trace of cyanide was pumped through the kidney for a time and the kidney then switched back to the heart-lung preparation.

FIG. 1.

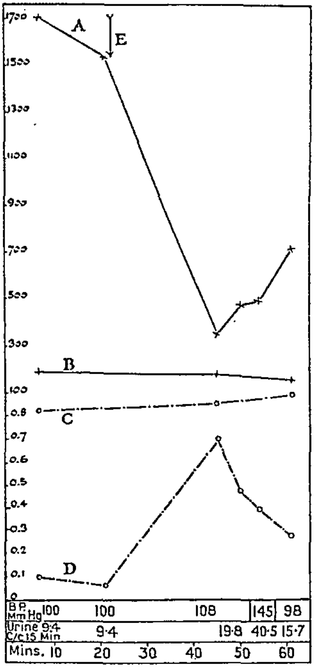


Apparatus employed for the purpose of asphyxiating the kidney suddenly and for a short period of time. For description see text. (E. H. Starling and E. B. Verney. From Proc. Roy. Soc. B., 1925, xcvii.)

The apparatus employed is shown in Fig. 1. The tube A comes from the heart-lung preparation and conducts the blood to the kidney supported in the water-jacketed funnel B. The outflow tube from this funnel passes on the one hand to the Dewar flask C, and on the other to the reservoir D. This reservoir is connected by means of a rubber syringe E and warming coil F to a T-piece in the arterial tube from the heart-lung preparation. Samples of urine are collected and some of the blood of the preparation placed in the reservoir D. To this is added a trace of NaCN, and the syringe, warming coil and tubing are then filled with the mixture as far as the tap G. The blood is being collected from the kidney in the Dewar flask C, the tap H being closed. At a given moment taps M and L are closed, taps G and H opened, and the syringe rhythmically compressed by hand so as to maintain the blood pressure constant at its original level. This is continued for some minutes, when by appropriate turning of the taps already mentioned, the kidney is switched back to its original circulation, and further samples of urine collected for analysis.

The results of one such experiment are plotted in Fig. 2. The temporary approach of the urine in its composition to that of the plasma is graphically represented as well as the speedy recovery which ensues on resuming the natural circulation. In some further experiments performed by Prof. Starling and myself[17] the kidney was perfused by means of a mechanical pump for longer periods of time with cyanided blood, and under these circumstances a pure filtrate of the blood plasma was obtained. The kidney failure was complete, but on reverting to the heart-lung circulation recovery of the organ set in. The kidney cannot be kept for long periods in a state of suspended animation by the use of cyanide. Although during the first ten minutes the filtrate obtained is perfectly free from protein, in the next five or ten minutes a small trace appears, and this amount gradually increases as time goes on. These experiments and those of Marshall and Crane demonstrate how sensitive the kidney is to its contemporary oxygen-supply, and how any interference with this supply speedily leads to failure of the renal units, partial or complete, and to the appearance of protein in the urine. It will be evident that such failure will be accompanied by a retention in the blood of those substances which are normally concentrated during the course of their excretion, and that the degree of this retention in the case of any particular substance will vary directly with the degree to which this substance is normally concentrated by the kidney. In chronic nephritis with polyuria it is the high threshold substances which accumulate in the blood stream.

FIG. 2.



The effects of asphyxia on the composition of the urine secreted by the isolated kidney of the dog. A = urine urea, B = serum urea in mg. per cent., C = serum chloride, D = urine chloride in g. per cent. (as NaCl). At E cyanided blood was pumped through the kidney for 10 mins. (E. H. Starling and E. B. Verney. From Proc. Roy. Soc., B., 1925, xcvii.)

Other experimental facts which have a bearing on the pathology of chronic nephritis will now be briefly mentioned. Firstly, that hypertrophy of the remaining tissue occurs as the result of removing some of the renal substance is well recognised. The hypertrophy, as Sapphir[18] has shown, is accompanied by the enlargement of the existing glomeruli—no new formation of glomeruli and tubules was seen. Secondly, as we saw in the last lecture, when a part of the renal tissue is functionally excluded, the reactiveness of the kidney to the addition of such substances as sodium sulphate and pituitrin to the blood stream is markedly diminished.

In the light of, and as far as possible in terms of the knowledge which has been gained on renal function as the result of physiological and pathological experimentation, it is now proposed to attempt to give a connected picture of the course of the disease of which polyuria forms so striking a symptom. We shall not consider the pathology of the so-called chronic parenchymatous nephritis with its prominent sign of œdema; rather shall we try to trace the course of that type of chronic nephritis which progresses to death without any sign, or one only of the slightest degree, of œdema. We assume the action on the glomerular vasculature of some toxin continuously or discontinuously applied, and leading to a gradual impoverishment in the blood-supply to the renal units. A diminution in the efficiency of the unit as a whole is thus produced. I can find no convincing evidence that in this disease any specific mechanisms within the individual renal unit are functionally impaired to an extent greater than the remaining mechanisms. Fishberg (8b) has come to a similar conclusion. I will illustrate my meaning more fully by referring to the actions of two drugs on the kidney. Caffeine, as Dr. Winton and I[19] have shown on the double heart-lung-kidney preparation, causes an increased flow of urine from the isolated kidney. The composition of this urine is, as far as we have been able to determine, the same as that of the urine produced by the control kidney when the perfusion pressure of this kidney is raised to such a degree that the diuresis so produced is the same as that occasioned by the action of caffeine on the other kidney. Caffeine diuresis, therefore, is a "pressure" diuresis, the individual units in the kidney being simply stimulated to do more work. Phlorhizin, on the other hand, picks out one particular mechanism, the sugar excretory mechanism, in the unit, and the compositions of the urine from each kidney at the same rate of urine flow would in consequence be different (De Boer and Verney).[3] There seems to be no evidence that in chronic nephritis the response of the individual units are affected in any way other than that resulting from a gradual or rapid fall in the efficiency of the whole unit. In the advanced state of the disease the units are in all probability in very different states of efficiency ranging perhaps from normal to zero. In the normal kidney the efficiency of the units composing it may be considered to be high and uniform, in the chronically inflamed kidney low and variable. We may *speculate*, then, somewhat as follows:—

The first effect of the hypothetical toxin on the normal kidney will be to lead to a reduction in the periods of quiescence of some or all of the units of which it is composed. The first reserves of the kidney have been requisitioned. Later the work thrown on the kidney during the day is unable to be completely dealt with, and the composition of the blood is brought back to its physiological optimum by an encroachment on the normal period of nocturnal rest. An increased urine flow during the day and during the night gradually becomes detectable, and is the expression of the increasing failure of the individual units of the kidney. The complete failure of some leads to the appearance of albumin in the urine. Their death with replacement fibrosis leads to a removal of that inhibition on the remainder which the work I described in the last lecture on the isolated kidney led us to postulate. The remaining units are now in a position to receive a greater pressure stimulus and they react to this increased stimulus, as we have seen from the experiments of Rose Bradford and from those on the isolated kidney, by secreting a more copious urine and one which approaches towards the plasma in its composition. Doubtless a work hypertrophy of these units also occurs, but such is insufficient to neutralise the loss of efficiency due to the gradual encroachment of the disease. No difficulty is being experienced, as we have seen in the experiments on the isolated kidney, in the excretion of chloride, but there results an increasing retention of urea and of those substances secreted by a similar mechanism. Eventually the *intrinsically* developed pressure stimulus is itself insufficient to bring about a sufficiently great response by those units which remain in activity. They are working at their maximum under the existing circulatory conditions, and a call is initiated for a further stimulus. This is responded to by an increase in the general blood pressure, and we have already considered the physiological mechanisms by which such a rise can be produced. Whether one of these known mechanisms is involved or not in the production of the high blood pressure of this disease, it is impossible to say in the present state of knowledge. With the death of still further units the work of the remainder can only be increased by a still further rise in blood pressure. The polyuria, then, will be persistent and, coincidently with the falling efficiency of those units which remain to function, its degree must become accentuated if any balance is to be maintained between the production and excretion of bodies such as urea and those eliminated by a similar mechanism. The balance becomes in time too negative to be compatible with life. Such a hypothetical picture of the gradual production and increasing intensity of the polyuria of chronic nephritis is based almost exclusively on physiological mechanisms in so far as they are at present known to exist in manifest or latent form. But the manner in which such mechanisms are correlated and integrated in the struggle to preserve the composition of the body fluids at their optimum is entirely unknown.

In concluding this lecture emphasis may be laid on what may be conceived to be the two essential functional changes responsible for the polyuria of chronic nephritis—viz., an increase in the pressure stimulus to secretion accompanied by a decrease in the efficiency of the kidney as a whole. That is to say, the composition of the urine from a normal kidney supplied with the same blood and secreting at the same rate, would exhibit a far greater recession from that of the plasma than the composition of the urine from a kidney which is the seat of this disease. And that the efficiencies, in this sense, of the individual units of the kidney are also diminished in this condition to varying degrees, would seem extremely probable.

Before I close I should like to thank you, Sir, and the College most warmly for the great honour you have done me in asking me to give these lectures, and although I have not faithfully adhered to the request of the Founder that the lecture should be read "between Michaelmas and Easter, on three days together, both forenoon and afternoon, on some dead body if possibly it can be procured, which shall then and there be dissected for the diseases treated of, and shall afterwards be buried," I hope that the observations which have been brought forward are not entirely irrelevant to the spirit in which this lectureship was founded.

THE ADMINISTRATION OF INSULIN IN SUSPENSION.

BY O. LEYTON, M.D. CAMB., D.SC., F.R.C.P. LOND.,
PHYSICIAN TO THE LONDON HOSPITAL.

DELIBERATION over the inadequate treatment of one disease occasionally leads to the benefit of patients suffering from another.

Many years ago the tortures suffered by children in whom pericardial adhesion had led to enormous hypertrophy of the heart made me seek some means of preventing the development of this condition. I thought that perhaps a non-absorbable oil such as liquid paraffin, if introduced during the period of effusion, might prevent the adhesion of the visceral and parietal layers of the pericardium. I began by introducing liquid paraffin into the pleural cavities of guinea-pigs and found that this was an efficient method of preventing adhesion when inflammation was produced by injection of aleuron. This has led to the use of liquid paraffin in pleural effusion and has benefited many patients suffering from that complaint, but has not been used to any extent in the much less common disease, pericardial effusion.

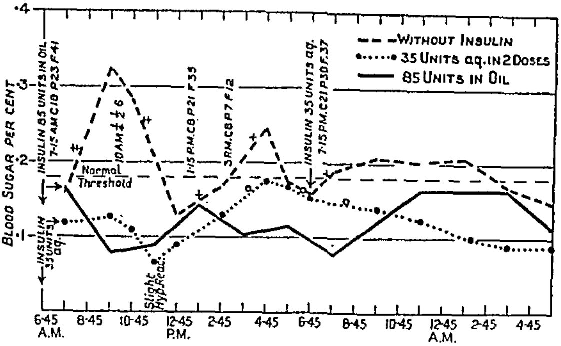
The origin of the work which I am recording in this paper, too, was indirect. In the treatment of diabetes insipidus the injection of five units of some extracts of pituitary gland will control the flow of urine for about four hours. If ten units be given the control may extend to six hours, but a contraction of the bowel is sometimes caused in susceptible subjects. Any further increase in the dose does not appreciably increase the length of time that the diuresis is controlled.

The Problem of Discontinuous Absorption.

Recently I have been supplied with extracts of pituitary gland which contain some quantity of antidiuretic material but very little vasopressin and oxytocin. Their injection does not lead to discomfort, but as they do not contain the substance which causes constriction of the blood-vessels, their absorption is rapid and, consequently, their action is not so prolonged as if they were slowly absorbed. It occurred to me that by making an emulsion I might delay absorption and control the diuresis for 24 hours by a single injection. The antidiuretic substance in pituitary extract might be difficult to prepare as a powder and therefore it seemed wise to transfer the observations to some other substance for a time and return to the treatment of diabetes insipidus at a later date.

I began experiments upon delay in the absorption of insulin and asked a manufacturer to supply me with the drug suspended in oil, thinking that by administering it in suspension its action could be made less intense and more prolonged. At first sight it seemed doubtful whether much would be gained, because it was generally accepted that the best way of giving insulin was to inject, shortly before a meal, the amount needed to katabolise the carbohydrates in that meal. Upon further consideration, however, one is forced to the conclusion that insulin is liberated continuously in the normal body, a larger supply being made available when the sugar in the blood rises above a certain level. The evidence for this conclusion lies in the following facts:—

CHART 2.



1. That neoplasm of the islands of Langerhans leads to death from hypoglycæmia.

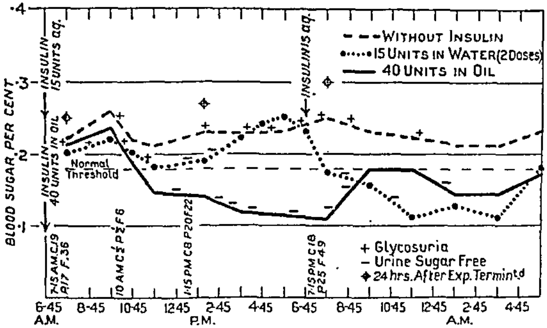
2. *That persistent hypoglycæmia* may occur in individuals who have never received insulin and who, upon exploratory laparotomy do not present any enlargement of the pancreas. These die if they are not fed with carbohydrate at short intervals.

3. *Cases of persistent hypoglycæmia* following the administration of insulin may occur. I have seen the sugar in the blood fall to 0·03 per cent. although insulin had not been given during the previous ten days. One imagines that in these cases the pancreas continues to secrete insulin slowly whilst there is some diminution in the activity of glycolytic ferment.

4. During sleep carbohydrate must be burnt, some from the glycogen stored in the liver and tissues, and some from the protein which is broken down, and for this purpose insulin must be supplied. In the normal individual the concentration of sugar in the blood during the night does not rise sufficiently high to stimulate the production of insulin. If carbohydrate katabolism were to cease during the night, ketosis would develop in some people.

If the pancreas were only to secrete insulin when the sugar in the blood rose above 0·16 per cent., then it would be difficult to imagine how hypoglycæmia could be produced in any other way than by the direct injection of insulin.

CHART 1.



Points in Practice.

Medium of Suspension.—At first it seemed to me probable that an emulsion might be made with the help of lecithin. This indeed proved possible, but the method was soon abandoned because the preparation was not stable.

I then asked for suspensions of pure dry insulin in oil, and Dr. S. W. S. Underhill was so good as to make some experiments in this direction. He found that if insulin were ground up with oils and then centrifugalised, some oils kept the insulin in suspension whilst others allowed it to settle. Probably this depends upon the specific gravity of the oil and also its viscosity and the fine state of division of the insulin.

Arachis oil suspended 60 units per cubic centimetre and possessed many properties which recommended it for use, but unfortunately a certain percentage of patients complained of pain after its injection.

Castor oil was then tried. This oil can suspend more than 100 units per c.cm. of the insulin prepared by British Drug Houses, Ltd. The specific gravity of this oil is about 0·964, against arachis oil 0·918. I found that castor oil did not give pain. No doubt a better medium will be used shortly but for the present it suffices; the suspension appears to be stable and the insulin does not deteriorate rapidly.

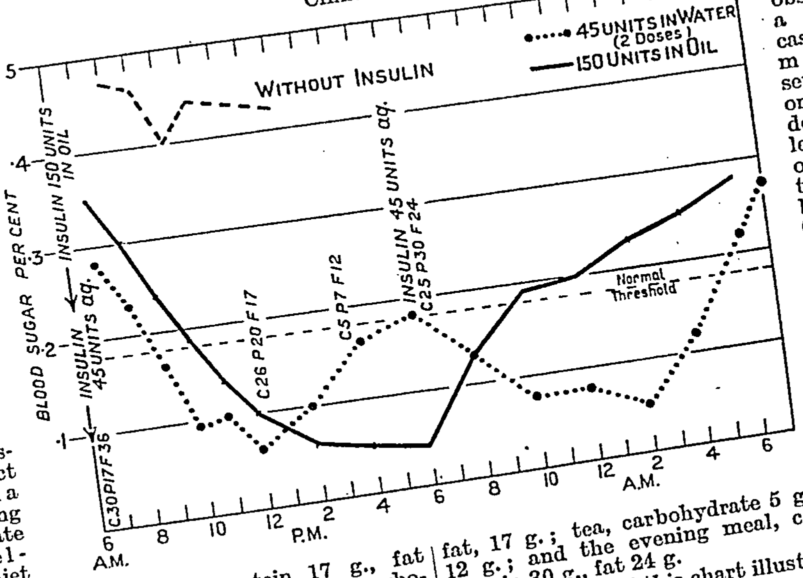
Method of Injection.—Obviously a viscid oil must be injected in a different manner to an aqueous solution. The points which should be observed are: (1) The oil should be warmed before injection, in order to reduce its viscosity (in very cold weather). (2) A thick needle must be used to draw it into the syringe. (3) A needle less fine than that used for aqueous solutions must be chosen for the actual injection; it should be short. (4) A screw-down syringe may be used if the muscles of the thumb of the injector be weak. (5) Lastly, but most important of all, the injection must *not* be intramuscular but subcutaneous. Experience has shown that the least discomfort follows injection under the skin of the abdomen, the injection being given before the patient rises in the morning.

Methods of determining which concentration of insulin in suspension is the most satisfactory.—In my opinion there is a tendency to make all patients conform to the same rules, a procedure which saves work but prevents attainment of the best results. For instance, many advise that the injection of insulin in solution be given 20 minutes before a meal; whereas investigation has taught me that some patients derive more benefit by receiving the insulin 5 minutes, others up to 90 minutes, before the meal. It is unreasonable to expect that all individuals will absorb oleum ricini given subcutaneously at the same rate, or that they will need the same flow of insulin into their tissues. I have therefore made observations with suspensions containing 100, 50, and 25 units per c.cm. When opportunity offers, it is undoubtedly wise to take samples of blood at short intervals and estimate the concentration of sugar in them. If the fall be rapid after the injection, then it would be wise to diminish the concentration of insulin in the oil and vice versa. If there be no opportunity of estimating the sugar in the blood, one of the two following methods may be used:—

1. After an injection of a suspension containing 100 units of insulin per c.cm., urine may be passed every two hours, and it is noted how long it takes for sugar to be excreted in recognisable quantity. This experiment should be continued for two or three days, and then the same dose of insulin should be injected in a larger volume of oil, and once more observations should be made to determine the period during which glycosuria is controlled. By trying different doses and different concentrations, glycosuria may be abolished completely, provided the diet is not greatly excessive and the patient is not completely resistant to insulin.

2. The urine during the 24 hours is collected, mixed, and measured, and the percentage of sugar in it estimated. This is repeated for three days, then the same dose of insulin, but in a different concentration, is given and observations are made as to whether the sugar excreted is increased or diminished. Usually this gives a clue of how it can be abolished completely.

CHART 3.



Illustrative Cases.

Chart 1 illustrates the effect of insulin upon a patient suffering from moderate diabetes mellitus. His diet consisted of: Breakfast, carbohydrate 19 g., protein 17 g., fat 36 g.; lunch at 10 A.M., consisting of carbohydrate 0·5 g., protein 0·5 g., fat 6 g.; dinner at 1.15 P.M., carbohydrate 8 g., protein 20 g., fat 22 g.; supper at 7.15, carbohydrate 18 g., protein 25 g., fat 49 g. This diet was arranged for two doses of aqueous solution of insulin—one was given at 6.45 A.M., and the second at 6.45 P.M. The dotted line shows the rise and fall of the sugar in the blood on that diet and doses of insulin. On the next day 40 units of insulin in oil were administered at 6.45, and the black continuous line shows the rise and fall of the concentration of sugar following that. In all probability the line would have been somewhat flatter if the midday meal had contained more carbohydrate and the evening meal rather less, but the comparison was made with the diet arranged from best results with the two injections. The third line shows the sugar in the blood when insulin has not been given, but apparently the effect of insulin is carried over for more than 24 hours and, on making estimations on the second day of the cessation of insulin, sugar in the blood is found to rise to 0·3 per cent. at 7.30 P.M.

Chart 2.—A patient suffering from somewhat more severe diabetes mellitus. The diet consisted of: Breakfast, carbohydrate 18 g., protein 23 g., fat 41 g.; morning lunch, carbohydrate 0·25 g., protein 0·5 g., fat 6 g.; at 1.15 P.M., carbohydrate 8 g., protein 21 g., fat 35 g.; at 3 P.M., carbohydrate 8 g., protein 7 g., fat 12 g.; at 7.15, carbohydrate 21 g., protein 30 g., fat 37 g.

After the morning dose of 35 units of insulin in solution, the sugar in the blood fell at 11 o'clock sufficiently low to produce symptoms of hypoglycæmia. Towards 5 P.M. the sugar in the blood approached the threshold, started falling, fell and continued to fall after the evening dose at 6.45 of 35 units of insulin. When observations were made upon the action of insulin in oil, the sugar in the blood started considerably higher than on the day chosen for observation with aqueous solution of insulin. The sugar in the blood fell well below 0·1 per cent., but not sufficiently low to give rise to symptoms of hypoglycæmia. Sugar in the blood remained below 0·15 per cent. until 11 P.M., when it rose to 1·7 per cent. I have little doubt that here, too, if some of the carbohydrate given at the evening meal had been transferred to lunch or tea, the sugar in the blood would not have risen so high. The third curve shows the rise and fall of the sugar in the blood when insulin was withheld. The sign O indicates that sugar was not found in the urine whilst the sign + indicates the presence of sugar.

Chart 3 was prepared from observations on a very severe case of diabetes mellitus, so severe that the omission of one dose of insulin led to symptoms of ketosis, whilst the sugar in the blood rose to 0·45 per cent. The patient's diet, however, was quite liberal. Breakfast consisted of carbohydrate 30 g., protein 17 g., fat 36 g.; the midday meal, carbohydrate 26 g., protein 20 g., fat, 17 g.; tea, carbohydrate 5 g., protein 7 g., fat 12 g.; and the evening meal, carbohydrate 25 g., protein 30 g., fat 24 g.

Examination of this chart illustrates very definitely that it is unwise to treat all cases in the same way. The patient was able to absorb insulin in suspension at too rapid a rate when injected in a concentration of 90 units per c.cm.; the effect was too transient, and insulin did not appear to be available for the metabolism of the evening meal. Although the dose of insulin was greater when the single dose was given than when the two aqueous doses were injected, nevertheless 50 g. more sugar were excreted. I concluded that it would be wise to reduce the concentration of the suspension. When the same dose of insulin was given in a suspension of 50 units per c.cm. 30 g. less sugar was excreted than when the two aqueous injections were given—that is to say, 80 g. more carbohydrate was utilised by reducing the concentration of the suspension.

The advantage I claim for the suspension of insulin is, that it will lead to a greater number of recoveries from diabetes mellitus. In my experience cases of recovery have been confined to those who, month after month, have kept the concentration of sugar in their blood continuously below 0·15 per cent. The prolonged action of the suspension will make this much less difficult. In all probability a number of drugs, in addition to insulin and the antidiuretic substance from the pituitary gland, may with advantage be administered in suspension.

It is with the greatest of pleasure that I express my thanks to my first assistant at the London Hospital, Dr. F. B. Byrom, who carried out numberless estimations and sacrificed many hours of sleep in order that the records of cases might be complete. Dr. J. L. F. Steele and Miss R. M. Simmonds, the dietitian to the hospital, rendered invaluable assistance.

PULMONARY NEOPLASMS.

A REPORT OF TWENTY-SIX CASES.

BY T. C. HUNT, B.M. OXF., M.R.C.P. LOND.,
ASSISTANT TO THE MEDICAL UNIT, ST. MARY'S HOSPITAL.

THE growing literature on the subject of intrathoracic tumours has shown from all sides an increased incidence of this condition in recent years. Though this increase is considered by some to be more apparent than real and is attributed, for example, by Fried [17] to better diagnosis, to a larger attendance at hospital, and to "increased human longevity," yet the careful and extensive reports of post-mortem statistics from many German and other authors have proved almost beyond doubt that a true increase has actually taken place. Statistics from the post-mortem records of St. Mary's Hospital are at present being collected and are shortly to be published. When it is realised that pulmonary neoplasm is found in approximately 7 per cent. of all autopsies on patients dead from carcinoma (various figures being 9·7 per cent. Wahl,[35] 10·7 per cent. Ferenczy and Matolcsy,[14] 5 per cent. Lubarsch,[25] 8·9 per cent. Biberfeld [6]) and ranks next in frequency only to carcinoma of the stomach, breast, uterus, and œsophagus (Lighty, Wright, and Baumgartner,[24] Gruber [19]) its importance can hardly be over-estimated. Since, furthermore, the percentage of early correct diagnoses is not generally greater than 33 per cent. (Sehrt [30] 4 per cent., Ferenczy [14] 25 per cent.), a further report of even a few cases only may be of some value.

The 26 cases here described have all been in the wards of St. Mary's Hospital at some period during the last six years (1922–28), and all have been examined post mortem. Twenty of them were in the Medical Unit wards (under Prof. F. Langmead); for permission to examine the notes of the remaining six patients I am indebted to Sir John Broadbent, under whose care they were.

The post-mortem findings confirm the now well-recognised fact that the overwhelming majority of intrathoracic neoplasms—often wrongly called "mediastinal tumours"—are in fact not mediastinal in origin—i.e., sarcomatous—but are of true carcinomatous nature. Of these 26 cases, for the histological examination of which my thanks are due to Dr. W. Newcomb, 21 are of the "oat-celled" type, three are composed of mixed polygonal and columnar cells, and two of squamous cells. They are thus, according to the views of the majority of workers on this subject, all carcinomata, the very common "oat-celled" type being considered either as a true bronchial mucosa tumour (Barnard,[4] Aschoff [2]), or as a growth of the alveolar lung epithelium itself.

Primary lung sarcoma and true mediastinal lymphosarcoma are undoubtedly rare. Staehelin [34] finds intrathoracic neoplasms to be almost all bronchial carcinomata. Barnard,[4] Fishberg,[16] Ferenczy,[14] Brandt,[7] Duguid,[10] Shennan,[32] and many others agree, and Sonnenfeld [33] saw only one case of sarcoma and affirmed that at least 95 per cent. of primary thoracic new growths are in fact bronchial carcinomata. Among 30 cases examined by Dr. Newcomb at St. Mary's Hospital only one was a fibrosarcoma of lung, one a true lymphosarcoma of the mediastinum, and one a teratoblastoma; the remaining 27 were carcinomata, 21 being of the "typical oat-celled" type, four of mainly polygonal-cell structure, and two of squamous epithelium.

Sex, Age, and Localisation.

Of the 26 patients here described 20 were men and only 6 were women. This shows a male preponderance of more than 3 to 1, which is even greater than has been found in many other series. Ferenczy [14] quotes 16 writers who all found a marked preponderance of male over female. Ewing [13] gives 71·9 per cent. as the percentage of men affected in 100 cases; Kikuth [23] and Dynkin [11] and Sachs [27] place the rates at 1·9 to 1 and 1·8 to 1. Ferenczy's own cases showed almost a 3 to 1 relationship; Rubenstone [26] found 8 men in 11 cases and Shennan [32] 27 in 31.

The average age was 50 years, the youngest being 27 and the oldest 79; this agrees with statistics of German writers who find the maximal incidence of these tumours between the ages of 50 and 60.

Sixteen—or 61 per cent.—originated, as far as could be determined, on the right side, and of these growths nine appeared primarily to have affected the upper lobe and seven involved either the whole lung or were mainly basal. An excessive incidence of right over left lung has been frequently noticed, Seyfarth [31] finding a ratio of 2 to 1. Holzers,[20] Briese's,[8] and Wolf's [36] figures agree, but Kikuth [23] and Marchesan found no appreciable difference. Many suggestions have been made to account for this increased liability of males to pulmonary carcinoma, particularly in the right lung, and any theory of ætiology must in some measure explain these facts. Some have thought that the more frequent respiratory "insults" that man, as compared to woman, must meet in his work, may account for this difference; road dust, tobacco, tar particles, cobalt, and arsenic in the air are some of the possible causal factors put forward. Duguid found that outdoor workers in Manchester seemed more liable to these tumours than those who worked in more sheltered conditions; Hudson [21] found a high incidence in grooms and stablemen. Shennan,[32] however, found nothing suggestive in the previous occupations of his patients, nor could Sehrt [30] connect these growths with any particular profession. Seyfarth's [31] patients were mainly labourers and land-workers, and 75 per cent. of Ferenczy's patients were also labourers, 48 per cent. of whom had had work in which the respiratory organs tended especially to be affected. Frommel [18] in France also noted that 29 of his 41 patients had been especially liable in their professions to inhalation of road dust. It seems that in recent years some new agent has appeared or increased in the air, which in some way makes the bronchial mucosa more liable to new growth formation.

The suggestion of Schwyter [29] (who found congenital malformation of the lung tissue in the neighbourhood of the growth in five cases out of eight) that developmental errors may be a cause of pulmonary carcinoma, remains unconfirmed. There is, however, some evidence to show that simple chronic irritation, as, for example, by chronic bronchitis, is an especial predisposing cause; influenza has been particularly blamed in this respect (Feyrter [15]) and tuberculosis has by others been considered as "the chief ætiological factor" (Ewing [13]) and "the forerunner" (Frommel [18]). The incidence of such conditions, however, does not appear to be higher as a whole in patients dying of pulmonary cancer than in those dying of other non-respiratory disease, and both chronic bronchitis and old or active tuberculosis are clearly not uncommon coincident findings in a large proportion of all post mortems. In these 26 cases a very definite history of somewhat severe previous respiratory affections was found in 13—i.e., 50 per cent., made up of influenza (6, including one patient who had also had pneumonia), chronic bronchitis (4), tuberculosis (2), pneumonia (2). Two of these had also suffered from asthmatic attacks. This is a somewhat high incidence and may possibly have some ætiological significance, though not to the same extent as was apparently the case in Berblinger's [5] series, or those of Feyrter or Frommel. In 12 of these patients it is possible to presume some particular liability to respiratory irritation, as they had been respectively: painters (4), engineers (2), dustmen (1), motor drivers (2), carpenter (1), brass-finisher (1), and coal-labourer (1). There was no case among stablemen as found by Hudson[21] and O'Donnell, nor a special preponderance among outdoor workers. Four patients only gave a history of excessive tobacco-smoking, and in no case was there any suggestive feature in the family history.

TABLE SHOWING THE CHIEF CLINICAL FEATURES AND PATHOLOGICAL FINDINGS IN 26 CASES OF PRIMARY NEW GROWTH OF LUNG.

Case.	Sex.	Age.	Occupation.	Previous history of respiratory disease.	Onset (first symptoms).	Hæmoptysis.	Effusion.	Length of life from onset of symptoms in months.	Type of carcinoma.	Situation of growth (probable origin).
1	M.	55	Taxi-driver	Nil	Pain→ dyspnœa	None	Purulent	4	Oat-celled	R. lower lobe
2	M.	65	Pensioner	Nil	Dyspnœa→ cough	Early	None	12½		R.(? upper) lobe
3	F.	40	Housework	Nil	Pain→ dyspnœa	Present	Hæmor.	17		L. lung (entire)
4	M.	32	Grocer	Nil	Aphonia→ dyspnœa	None	None	8		L. lung (hilum)
5	M.	51	Salesman	Cough (10 years)	Pain→cough	Early and continued	„	12	Polyg. and col.-celled	L. lung (upper)
6	F.	59	Saleswoman	" Always chest trouble."	Pain→cough	None	„	—	Oat-celled	R. lung (root)
7	M.	40	Postman	Nil	As "bronchitis"	Severe	Hæmor.	6		R. lung (root)
8	M.	46	Painter	Influenza (frequent)	Aphonia→ cough	None	Bilateral	3		R. and L. root
9	M.	46	Clerical (G.P.O.)	Nil	Bronchitis→ "swelling of neck"	Late	Present	6		R.(? upper) lobe
10	M.	43	Engineer	Influenza, phthisis, bronchitis	Stridor→ dysphagia	Present	None	5	Polyg. and col.-celled	R. lung (? upper lobe origin)
11	M.	57	Brass-finisher	Bronchitis (6 years)	Dyspepsia→ dysphagia	„	„	3	Oat-celled	R. lung (lower)
12	F.	54	Housework	Influenza	Dyspnœa	None	Hæmor.	15		R. lung
13	M.	63	Electrical engineer	Phthisis	Œdema of arm →cough	Early	None	4		R. upper lobe
14	M.	48	Motor-driver	Nil	Cough	„	Present	6		L. lung

25	M.	47	Painter	Pneumonia	Vomiting→ "bronchitis"	Present	„	4	Oat-celled	R. upper lobe
26	M.	44	Railway guard	Nil	Pain→coma	None	„	6	Squamous-celled	R. lower lobe

Hæmor., hæmorrhagic. Polyg., polygonal; col., columnar.

Special Features.—CASE 5: Old tuberculosis both lungs (extensive). 6: Death from pulmonary embolism. 8: Origin probably on right side. 10 and 11: Death from profuse hæmoptysis. 12: Collapse and death after aspiration of chest. 14: Bronchiectasis, gangrene, empyema, septicæmia. 16: Pericarditis and heart failure. 21: Accidentally found at autopsy; death from other causes. 23: Pericarditis and heart failure. 24: Secondary deposit in right cerebral cortex. 25: Diagnosed "aneurysm." 26: Secondary deposit in left cerebral cortex.

Course, Symptoms, and Signs.

The course of bronchial carcinoma has been described as slow and gradual, and this may well be true, since it is rare for patients to come under observation until the growth is well advanced. At first the condition causes few symptoms and there is no tendency to cachexia, loss of weight, or anæmia; in our patients the strikingly good general condition was noticeable until the late and final stages of the disease, and in several instances heavy work was continued until within a few weeks of death. When once it has made itself felt, however, bronchial carcinoma takes a rapid course, and the average length of life in these patients from the first definite symptom was almost exactly six and a half months. The shortest duration was one and a half, the longest 17 months. Sonnenfeld[33] found a course—dating from the first symptom—of from three months to three years, but no definite data exist as to the actual total duration from the commencement of the growth itself. Fried[17] emphasises the slow growth of these tumours and considers this to be one reason why metastases are so common, but though there is doubtless a relatively long symptomless latent course, it is difficult to believe that the average total duration can be more than two years.

Early diagnosis of pulmonary carcinoma is obviously not of the same hopeful importance as it is, for example, in the case of gastric or mammary cancer, though Sauerbruck[28] Edwards,[12] and Lilianthal have discussed the advantage of thoracotomy and if possible lobectomy early in the disease. From a prognostic point of view, however, it is a vital consideration. A few features only will be here considered. The early symptoms of the condition frequently resemble pulmonary tuberculosis, and it is often diagnosed as such, particularly by X ray evidence (Uspensky[37]). The onset, however, appears often to be with pain, which is not very common in tuberculosis. Among these 25 patients (one, in whom a small symptomless growth was found accidentally at autopsy, is omitted) nine, or 36 per cent., complained at first of pain only; in five cases this preceded any other disturbance by many weeks and was of a dull, aching character, spreading to the shoulder-blade of the affected side and in two cases down the arm. This is unlike tuberculosis and is very easily mistaken for fibrositis or "neuralgia." It is probably due to pleurisy over the growth, and in a few cases to nerve-pressure with referred pain via the phrenic nerve to the shoulder. Five of these eight patients—or 62 per cent.—either at once or later developed a pleural effusion, so that pleural pain may well account for the majority. In only four cases was a rub heard. Many other cases began as "influenza" or "bronchitis," and a strikingly frequent mode of onset was an acute attack of illness with cough which was invariably diagnosed as "influenza" or "bronchitis"; this kept the patient to his bed for a short time 7 to 21 days—and was followed by a return to work for a few weeks, then a "recrudescence" of the original "influenza," and thenceforth a steady and rapidly progressive course until death. Six of these cases showed exactly this history, and the original acute attack again appears to be due to the first affection of the pleura as the growth spreads outwards, though in no case was it quite typical of an ordinary simple pleurisy. Three patients complained of dyspnœa from pressure on a bronchus as their first symptom (two with cough), and seven suffered from the effects of pressure or other structures—i.e., two from hoarseness and loss of voice (recurrent laryngeal nerve), two from dysphagia (œsophagus), one from stridor (trachea), and two from œdema of the arm or face (large veins). No clear prognostic import could, however, be deduced from the mode of onset in these patients, though those whose illness began with "bronchitis" lived on an average three months longer than those in whom it started with primary pressure symptoms. In no case was hæmoptysis the earliest symptom, as is considered to be frequent by Sonnenfeld (50 per cent.), and indeed the so-called typical red-currant jelly sputum appeared to be actually rare in this condition (see also Abraham [1]). Of these patients, 12—or 48 per cent.—showed during the disease either blood-streaked sputum or a severe hæmoptysis; in five it was an early event, in two it was the immediate cause of death. Cough and dyspnœa were both absent in one patient only, who complained of some pain and dysphagia, was treated by gastrostomy, and died suddenly from a profuse hæmoptysis. The rapid progress of the dyspnœa in the later stages of the disease was very typical, and indeed at this time the diagnosis could often be made at sight. The swollen, congested face and arms, the constant restlessness, and anxious, worried expression formed a characteristic picture.

The physical signs were most variable. In 12 of these patients they were those of effusion; in six the effusion was present on first examination, and in five it developed later in the disease. One patient was operated upon for empyema, and in five cases the fluid was hæmorrhagic. The presence or absence of an effusion did not appear, however, to exert any influence on the duration of the disease, but since it was present in 48 per cent. of these patients an otherwise unexplained effusion in an elderly patient must always arouse suspicions of a growth of the lung. Staehelin [34] found that one-third of his patients already had a pleural effusion when they first came to a doctor. The position of the heart's apex-beat is in such cases often misleading, and indeed in all cases of pulmonary carcinoma appears to be an unreliable guide. In these 25 patients the apex-beat in five was displaced towards the side of the growth, in ten it was displaced towards the healthy side, and in ten no appreciable change was found. Abraham [1] also noted that the displacement of viscera towards the affected side did not exclude growth, and in two patients in this series in which an actual effusion was present such retraction was noticed. Marked flattening of the chest was noticed in three patients only, but impaired movement on respiration was found in sixteen and dullness on percussion in all, either early or late. Bulging of the chest wall occurred in four and an external growth was seen in three. The auscultatory signs varied with the stage of the growth and with the presence or absence of associated infection or effusion. Five patients had the typical signs of a cavity, but the commonest findings were weak or absent breath-sounds with a few coarse râles and slightly diminished vocal resonance. Clearly there can be no constant group of signs typical of pulmonary new growth. Enlargement of veins of the neck or over the thorax, for example, was only noted as an early sign in five patients (or 20 per cent.) and palpable enlarged glands in the neck or axilla occurred only in eight (or 31 per cent.) during the whole course of the disease.

Diagnosis.

Early diagnosis must depend largely upon X rays. The sputum was in no case sufficiently characteristic, and in only three patients did examination of the pleural fluid give definite assistance by showing the large endothelial cells said to be typical of these growths. The physical signs alone were seldom sufficient in themselves to establish an early diagnosis. Fishberg [16] considers that the examination is incomplete unless, besides X rays and lipiodal injection, bronchoscopy with removal of a portion of tissue has also been carried out. When fluid is present X rays alone are especially untrustworthy and can seldom give definite indication of the cause of the effusion. According to Kirklin [22] the three radiological characteristics of early malignant disease are density of the hilum, atelectasis, and bronchiectasis.

The most frequent sources of difficulty in diagnosis in this series were tuberculosis and mediastinal tumour; growths that start close to the hilum, beginning with early pressure signs, especially resemble growths of the mediastinum. Two cases were mistakenly diagnosed as carcinoma of the œsophagus, one as subphrenic abscess, and one as empyema. In two patients a primary pulmonary growth was unsuspected, since the clinical picture was entirely dominated by the neurological condition caused by the presence of secondary deposits in the brain. One presented a complete hemiplegia (growth in the right cerebral cortex), the other had epileptiform convulsions and coma without definite localising signs (growth in left cortex). One patient was thought to have an aortic aneurysm, and in one the growth—a very small "oat-celled" carcinoma—was discovered by chance at autopsy. The frequency with which these patients present themselves as "neurological cases," with symptoms due to metastases in the central nervous system, has been emphasised by Fried, who ascribes it to a hæmatogenous spread dependent upon the anatomical relations of the vessels of the lungs and brain. Of his 10 patients, 9 complained of nervous symptoms. Lubarsch [25] also described five cases in which the condition first showed itself through cerebral metastases, and Seyfarth [31] mentions as many as 32.

In 18 the correct diagnosis of intrathoracic neoplasm was made before death, but since the rarity of true mediastinal lymphosarcoma has been realised our difficulty lies less in determining the nature of the growth than in locating more precisely its site and point of origin. Unfortunately in this series no light can be thrown upon the prognostic difference between growths originating presumably in the bronchi themselves and those arising in the pulmonary alveoli.

Treatment.

The only treatment possible has been palliative; nearly all the patients were more comfortable propped up well forward in bed, and some ingenuity was often necessary to maintain them in a comfortable position. Deep X ray therapy in most cases produced temporary improvement and lessening of symptoms, but did not seem appreciably to check the course of the disease; severe transitory "reactions" occurred in two cases and very striking "remissions" in three. A more detailed list of these cases is shown in the table and a short bibliography of some papers on this subject is appended.

Summary.

1. Twenty-six cases of pulmonary carcinoma are described, 21 being histologically of the "oat-celled" type. 2. No distinction could be made clinically between the "oat-celled" type and lung tumours of polygonal, columnar, or squamous-celled type. 3. The ratio of men to women affected was, approximately, 3 to 1. 4. A somewhat marked incidence of previous lung affections, especially influenza and bronchitis, was found. 5. No connexion between the incidence of the growths and previous occupations could be traced. 6. Especially common modes of onset were (1) with pain in the chest alone; (2) with *an acute febrile attack of "influenza" followed by a* temporary return to work. 7. Early pressure signs were frequent, and should not necessarily suggest mediastinal tumour rather than a pulmonary growth. 8. The average age of the patients was 50, and the duration of the disease (from first symptom to death) was six months. 9. Hæmoptysis occurred in 48 per cent. and pleural effusion in 48 per cent. of these patients. 10. The position of the heart's apex was variable and was unaltered in 40 per cent. 11. Metastases were not a frequent cause of symptoms.

I should like to express my gratitude to Prof. F. S. Langmead, at whose suggestion this paper was prepared, for permission to examine the patients under his care and for his assistance in the consideration of the cases.

BERKSHIRE CONTRIBUTORY SCHEME.—Last year £27,452 was collected by the Berkshire and Associated Hospitals Aid Committee, an increase over the preceding year of £3299, which constitutes a "record." The formation of five new branches partly accounts for this rapid growth. The expenditure on administration was £1407.

A POOR-LAW COUNTRY HOME.—The Birkenhead guardians have bought for £10,000 Sir Henry Vernon's residence, Eastham House, in the Wirral District, and have opened it as a home for aged and infirm poor and for convalescent patients from Tranmere Infirmary. The house which stands in 50 acres, has an oak-panelled staircase carved with scenes from *The Canterbury Pilgrims.*

OBSERVATIONS ON THE TREATMENT OF TWO CASES OF POLYCYTHÆMIA VERA WITH PHENYLHYDRAZINE HYDROCHLORIDE.

BY W. MACKAY, M.B. GLASG.,
PHYSICIAN TO OUT-PATIENT DEPARTMENT, GLASGOW ROYAL INFIRMARY; JUNIOR ASSISTANT TO MUIRHEAD PROFESSOR OF MEDICINE, GLASGOW UNIVERSITY.

FOR some time past it has been recognised that phenylhydrazine hydrochloride has the power of destroying red blood corpuscles, and it has been used by many investigators to produce anæmia in animals. Within recent years it has been exhibited for the same purpose in the treatment of polycythæmia vera. Eppinger and Kloss, while stating that there was an increased formation of red corpuscles in the bone-marrow in this disease, produced evidence to show that the process of red cell destruction was not so active as would be expected; therefore in 1918 they prescribed phenylhydrazine with the idea of stimulating the destruction of erythrocytes. They first administered the drug subcutaneously in solutions varying in strength from 1 per cent. to 10 per cent., but later they obtained the same results on giving the drug by the mouth. They considered this method of treatment to be an almost harmless means of reducing the number of red blood corpuscles and hæmoglobin. Since then it has been used by Taschenberg, Owen, Brown and Giffen, and others with very similar results. In all cases the red cells and hæmoglobin were diminished, while in some a moderate leucocytosis was produced. Jaundice appeared in the course of treatment, the urine became very dark in colour, and in a number of cases urobilin was present. It was noted by Owen, and Brown and Giffen that the red corpuscles continued to diminish in number for a varying period after the drug was stopped. In most of the cases reported the signs and symptoms of the disease returned in from two to six months, and the treatment had to be repeated. Taschenberg observed in his case that the desired effect did not always take place after repeated courses of treatment, and he thought that the drug might in some way harm the liver. Wells described lesions appearing in the liver when animals were poisoned with sulphate of hydrazine. Bodansky, working with phenylhydrazine, showed that it had a destructive action on the liver, and that variations in the lævulose-tolerance curve could be taken as an index of the toxic action of phenylhydrazine on the liver cells.

Recently we had the opportunity of treating two cases of polycythæmia vera with phenylhydrazine hydrochloride, and we resolved to record the histological changes in the blood. In the course of treatment certain other observations were made on changes taking place in the blood plasma, and in the resistance of the red cells to hypotonic saline.

CASE 1.—A male, aged 42, an engineer, first came under observation in 1922 complaining of giddiness, headache, and weakness in the legs which prevented him from working. The ears, lips, and tongue were cyanosed and the breath had a peculiar odour. The systolic blood pressure was 152 mm. of mercury, but the heart was not enlarged. The spleen could not be palpated, although the splenic area was enlarged to percussion. There was nothing of note in the past health or family history. The Wassermann reaction was negative. Three and a half months later the spleen was palpable at the costal margin. In August, 1925, the face, ears, lips, nose, and fingers had a deep crimson colour, and by December of that year the spleen could be palpated 1½ inches below the costal margin.

On admission in 1922 the red cells numbered 9½ millions, and from that date until readmission to hospital in April, 1927, the red cells varied between 7 and 9 millions. During these five years he had been taking benzol by mouth more or less continuously.

On April 26th, 1927, he was readmitted. He had been unfit for work, and on examination the cardiac area was found to be slightly larger than normal and the radial arteries palpable. The spleen reached forwards and downwards to the level of the umbilicus 1 inch from the middle line, and the red cells numbered 9 millions. He was given grs. 3 of phenylhydrazine hydrochloride twice daily and, on three occasions at weekly intervals, 7 oz. of blood were withdrawn from one of the veins of the arm. In four weeks the red corpuscles were reduced to 5 millions and he was dismissed from hospital feeling very well. He reported frequently and phenylhydrazine hydrochloride was prescribed from time to time, as the blood count indicated, in doses varying from gr. ½ to grs. 2 twice daily. By May, 1928, the red cells numbered 6½ millions and, as he was not feeling fit, he was again readmitted for observation on May 25th. He was treated with a fresh supply of phenylhydrazine hydrochloride, for it was thought that the old stock had deteriorated and was not having the desired effect. This ultimately proved to be the case. The following table shows the dosage given and the response obtained after admission to hospital on May 25th, 1928.

(*g*) Phenylhydrazine hydrochloride stopped.

CASE 2.—A male, aged 74, an artist by profession, was admitted to hospital after a hæmatemesis which had occurred 14 days previously. On other occasions he had vomited blood, and one year earlier he had had a hæmaturia, cystoscopic examination at this time failing to reveal any cause for the bleeding beyond some congestion of the prostatic venous plexus. Six months later he had developed phlebitis in both legs. For the past 15 or 20 years he had been subject to attacks of indigestion. The face and lips were well coloured, but there was no cyanosis. The area of cardiac dullness was within normal limits, but the spleen extended downwards to about three inches below the costal margin. The Wassermann reaction was negative. The dosage of phenylhydrazine hydrochloride given and some of the changes observed in the blood are shown in Table II.

The phenylhydrazine hydrochloride was given in gelatin capsules and administered by mouth, the amount varying from grs. 4½ to grs. 6 daily. Usually the dose prescribed was grs. 1½ thrice daily to begin with, then it was increased to grs. 3 twice daily until the red corpuscles began to fall in number, when the dose was reduced to grs. 1½ thrice daily. This was continued until the red cells numbered about 4½ millions, when the drug was discontinued. In Case 1 the total amount of phenylhydrazine hydrochloride prescribed over a period of 12 days was grs. 63, and in Case 2, in 20 days, grs. 103½ were administered. The red cells began to decrease in number in the first case after grs. 10½ had been given, while the second case required grs. 70½ before any response was evident. It therefore appears that some individuals respond more quickly than others to the treatment, but it should be noted that Case 1 was aged 48, and Case 2 aged 74. The exhibition of the drug was controlled by frequent blood counts and, in view of its toxic action on the liver cells, as shown by Wells and Bodansky, lævulose-tolerance curves were made before, during, and after treatment. The curves obtained were never indicative of hepatic inefficiency.

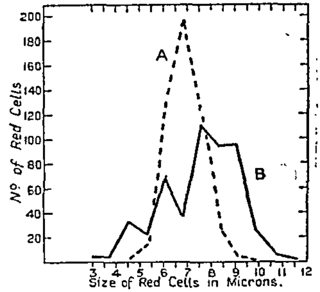
Remarks.—Fourth and thirteenth days after admission: bilirubin less than 0·25 units. Twentieth day: bilirubin 0·5 units. Twenty-fourth day: bilirubin 1 unit.

Effects on the Blood.

From the tables of blood counts it will be seen that the red cells became reduced in number, and that the diminution continued for some time after the drug was stopped, for a period of ten days in the case of the first patient and five days in the second patient. The latter at first responded very slowly to the action of the phenylhydrazine, but when the red cells did begin to decrease they did so very rapidly, falling from 7·7 millions to 2·7 millions in 12 days. At first the fall in the percentage hæmoglobin was more or less parallel with the fall in the number of red cells, but as the anæmia became more profound, and later when the red corpuscles were beginning to increase in number, there was an increase in the colour-index. This was most noticeable in Case 2. On the twenty-ninth day after admission there was an increase in the mean



Price-Jones curves showing the greater variation in size and an increased proportion of large red cells in the circulation three days after treatment had been discontinued. A is the curve obtained the second day after admission—i.e., before treatment. Mean diameter of red cells 6·95 μ. B is the curve on the twenty-ninth day after admission. Mean diameter of red cells 7·72 μ.

diameter of the red cells as compared with the mean diameter before treatment was commenced.

Examination of blood films from day to day showed the gradual appearance of nucleated red cells (normoblastic in type), reticulocytes, polychromasia, poikilocytosis, and anisocytosis, all of which became more marked as the anæmia became more profound. An increasing proportion of the red cells were megalocytes, and as time went on the blood gradually assumed a megalocytic character. This is shown graphically in the figure, in which two curves, plotted after the fashion of Price-Jones, show the differences in size (mean diameter), and the alteration in the proportion of cells of various sizes, between 500 red cells on the second day of admission—i.e., immediately before treatment was commenced, and another 500 red cells on the twenty-ninth day—i.e., three days after the phenylhydrazine had been discontinued.

There was a tendency for the blood platelets to increase in number during treatment, and the reticulocytes increased as the anæmia became more marked. While the phenylhydrazine hydrochloride was being given there was a progressive leucocytosis in each case, but as soon as the drug was discontinued the white cells immediately began to return to the level, or even below the level, at which they had been before treatment started. The leucocytosis was entirely due to cells of the granular series, particularly the neutrophil polymorphonuclear leucocyte. There was, however, a slight percentage increase in the number of basophil and eosinophil polymorphonuclear cells. In each case there was an absolute and relative diminution in the number of lymphocytes.

In the course of treatment jaundice appeared, first in the scleræ and a few days later becoming generalised over the body, but it was always slight. The van den Bergh reaction was never of the direct type, and the indirect reaction showed a gradual increase in the bilirubin content of the blood serum as the jaundice became more widespread. (Tables II. and III.) After treatment was discontinued, the icterus cleared up within a few days in each case. Table III. also shows the changes in the blood nitrogen and the blood cholesterol in Case 1. There was a slight increase in the former while the plasma cholesterol fell from 160 mg. per 100 c.cm. to 70 mg. per 100 c.cm. during the administration of the drug.

(*a*) Treatment commenced. (*b*) Treatment stopped.

Observations on the fragility of the red cells did not reveal anything unusual in Case 2, but in Case 1 on the third, fourth, and seventh days lysis commenced in 0·45 per cent. salt solution, on the eleventh day in 0·35 per cent. salt solution, and on the fourteenth and eighteenth days in 0·4 per cent. salt solution. Lysis was invariably complete in 0·3 per cent. salt solution. It appears, therefore, that there was a tendency to some slight increase in resistance to hypotonic saline solution. In the experimental anæmias produced in animals by phenylhydrazine the red cells show an increased resistance to lysis in hypotonic salt solution (Muir). Taschenberg noted in his case that, with each successive course of treatment, more phenylhydrazine was required to bring about a reduction in the number of red cells, which reacted normally to hypotonic salt solution; he concluded that the red corpuscles acquired a special resistance to phenylhydrazine. No definite statement can be made about this, but Case 1 has had phenylhydrazine at intervals over a period of 16 months, and still reacts to suitable doses of the drug, provided it is fresh.

During the treatment of both patients the most remarkable change found in the urine was in its colour, which became very dark and at times almost black. The nature of this change is not understood. Urobilinogen was never found, and positive tests for urobilin were obtained only in Case 1 on three occasions—on the seventeenth, eighteenth, and nineteenth days after admission. There was a gradual increase in the output of urinary urea from 1·7 per cent. before treatment to 2·7 per cent. after treatment in Case 1, and in Case 2 the urea increased from 2·1 per cent. to 2·7 per cent.

Complications.

While in hospital, Case 1 became free from his symptoms as the red cells were reduced and no complications arose, despite the fact that he was allowed up while the phenylhydrazine was being given. He was dismissed on the twenty-second day feeling fit and well. The red cells at that time numbered 3·2 millions. No alteration was noted in the size of the spleen. Ten days afterwards he complained that his right ankle was swollen, red and tender, and the same thing occurred in the left ankle nine days later. At this time no phenylhydrazine was being administered. No phlebitis was observed, and the swelling and pain in the joints cleared up satisfactorily with a few day's rest. The red cells gradually increased until, on the ninetieth day after admission, they numbered 9·1 millions. He complained of flushing of the face, pains in the head, and tingling of the fingers. Fifteen ounces of venous blood were withdrawn, and he was given phenylhydrazine hydrochloride grs. 3 daily. A week afterwards the red cells were 6·1 millions, and the drug was continued until in another 18 days the red cells had fallen to 4·4 millions, when it was stopped. The red cells are again increasing, and it is anticipated that before long the patient will require another course of treatment. After treatment had been stopped, but while he was still in hospital, Case 2 developed a phlebitis in the right great saphenous vein on the twenty-ninth day after admission, when the red cells were 2·6 millions. This took some time to clear up, and he was not dismissed from hospital until one month later. When he reported ten weeks later the red cells numbered 5·7 millions, but he was keeping remarkably well and free from symptoms. No further doses of phenylhydrazine have yet been prescribed.

The above findings agree more or less closely with those reported from time to time by the other observers. Taschenberg, and Brown and Giffen mention the occurrence of thrombosis during treatment, but, as the latter writers also point out, thrombosis is common in cases of polycythæmia vera without treatment. It is a noteworthy fact that in Taschenberg's case and in our Case 2 there was a previous history of thrombosis and hæmatemesis. Brown and Giffen suggest that under treatment there is liberation of thromboplastic material which might predispose to thrombosis. In this connexion it is interesting to note the statement by Rosenthal regarding the blood-platelet factor and splenectomy. He points out the relationship between thrombosis and an increased platelet count in certain cases showing Banti's syndrome, and he mentions one such case in which, after excision of the spleen, the platelets rose to over 1 million and thrombosis supervened.

After this there was a diminution in the number of platelets. In Case 2 the platelets numbered 988,200 five days before the onset of the phlebitis; 13 days afterwards the platelets numbered only 217,200. Brown and Giffen also mention the possibility of a platelet factor being associated with thrombosis but, in three of their cases in which the blood-platelets were counted, the count was normal in two, while in the third the count was high at the beginning of treatment and gradually diminished to normal.

The question of possible damage to the liver from poisoning by phenylhydrazine is regarded as important by most of the other observers, mainly on account of lesions produced in the liver in experimental work on animals with hydrazine compounds, and also on account of the hepatic cirrhosis found on post-mortem examination in the case of polycythæmia reported by Levi, which had been treated with phenylhydrazine for one and a half years. But it is well known that cirrhosis of the liver may occur as a late complication in polycythæmia vera where no phenylhydrazine has been given. Levi considers that the cirrhosis is related to destruction of red cells, and that where phenylhydrazine is administered this destruction is increased and may hasten the onset of cirrhosis. Owen is inclined to regard the leucocytosis as an early sign of toxic damage to the liver cells, and therefore advises that treatment be discontinued if the leucocytosis becomes markedly increased. In the seven cases treated by Brown and Giffen, and in the two cases recorded above in which various tests of hepatic efficiency were carried out, no evidence of liver damage was found. Perhaps sufficient time has not yet elapsed to judge the effect of repeated courses of treatment, but Case 1, after six courses of phenylhydrazine within 16 months, shows no sign of hepatic inefficiency and, indeed, is now able to do light work as a night watchman.

Conclusion.

There seems to be no doubt that phenylhydrazine given by mouth is an effective agent in bringing about destruction of red cells. It is not known whether the destructive process is intracellular or extracellular in nature, but evidence of the hæmolytic effect of the poison is afforded by the increasing bilirubin content of the blood serum and the occasional appearance of urobilin in the urine. The action on the hæmopoietic system is not clear. From the experimental anæmias produced in animals phenylhydrazine appears to inhibit regeneration of the blood cells in some way. While that may be so, the data given above indicate, in the case of the erythropoietic system, an active regeneration rather than an inhibition. This is shown by the early appearance of reticulocytes, megalocytes, and polychromasia. Whether this activity is due to direct stimulation of the erythropoietic tissues, or whether it is secondary to the red cell destruction, cannot be definitely stated, but it is probable that the increased activity is a response to the demand for red cells to replace those destroyed by the phenylhydrazine. In common with many other drugs and poisons, phenylhydrazine seems able to call forth a leucocytosis, and this is thought to be due to some chemiotactic influence stimulating directly the leucoblastic tissues.

While the beneficial action of phenylhydrazine hydrochloride is only temporary, its use in the treatment of polycythæmia vera is justified by the feeling of well-being and the freedom from symptoms which it produces, always provided that its exhibition is controlled by frequent blood counts, and that it is discontinued when the number of red cells reaches the neighbourhood of 4·5 millions. While as yet there is no definite contra-indication, it must always be remembered that phenylhydrazine hydrochloride is a protoplasmic poison, and should be used, therefore, with care and respect.

I gratefully acknowledge my indebtedness to Prof. W. K. Hunter for permission to treat these two cases and publish the results. My thanks are also due to Dr. C. M. Fleming for her kindness in carrying out the blood nitrogen and blood cholesterol estimations mentioned in Table III.

PITUITARY CACHEXIA IN A CASE OF TABES DORSALIS.

BY T. S. GOOD, M.A. OXF., M.R.C.S. ENG.,
MEDICAL SUPERINTENDENT TO THE OXFORD COUNTY AND CITY MENTAL HOSPITAL, LITTLEMORE;
AND
K. O. NEWMAN, M.D. VIENNA,
PATHOLOGIST TO THE HOSPITAL.

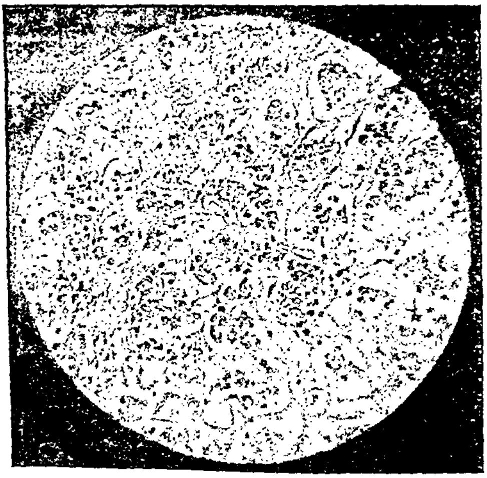
WITHIN recent years a great deal of attention has been paid to an affection of the pituitary gland, described as "Simmonds's disease," or "pituitary cachexia." The nosology of the glands with internal secretion is so complex and their physiology so incomplete, in spite of the overwhelming volume of literature on the subject, that a brief outline of Simmonds's disease seems justified. In 1914 Simmonds[1] described a case of total necrosis of the anterior, i.e., glandular part of the pituitary gland, caused by a post-partum septic embolus in the arterial supply of the lobe, which is separate from the supply of the posterior lobe. The most outstanding clinical feature was an extreme cachexia, accompanied by a senile aspect, loss of axillary and pubic hair, general nervous disturbances, and reduction in size of the abdominal organs (microsplanchnia). The atrophy of the anterior lobe can be caused by a variety of processes, such as compression through cysts and tumours, functional exhaustion through pregnancy, as claimed by Maresch[2] and Budde,[3] tuberculous infection, as described by Schlagenhaufer,[4] and, probably most important of all clinically, luetic affections. A number of cases of the last-named are reviewed by Jaffé,[5] and a general survey is to be found in the work of Kraus[6] and others. The symptomatology of the disease, excellently described by Redlich,[7] is very wide, though some salient features seem to be unmistakable. Trophic-vasomotor changes of the skin, as in myxœdema and sclerodermia, as well as in numerous cases total loss of teeth without caries, have been mentioned by Graubner,[8] Reye,[9] and Zondek.[10] Stress has been laid, as mentioned before, on the loss of hair under the armpits and pubic hair, as well as on the loss of hair on the trunk, while the growth of hair on the head and face remained unaffected. In our case there was a distinct loss of hair on the head, while the rest remained comparatively intact.

One might summarise the majority of symptoms under the heading of "hypofunction"; the pronounced muscular weakness, low body temperature, low blood pressure, and lowering of hæmoglobin, sometimes accompanied by marked eosinophilia. Lowering of basal metabolism, water- and mineral-metabolism, and particularly disturbances of sodium chloride excretion, are reported by various authors. Cessation of the menses in women and a premature senility in both sexes, caused by atrophy of the genital organs, are almost constantly described. The nervous and psychological symptoms are dominated by a certain torpor and apathy, very often coupled with marked sleepiness, which is, as repeatedly mentioned by Cushing, a frequent occurrence in pituitary tumours as well as after experimental removal of the pituitary gland. The neuropsychological symptoms are so marked and constant that such an experienced observer as Redlich (loc. cit.) tentatively suggests the term of "præhypophysial depression." Narcolepsy in Simmonds's disease has been described by Pennetti.[11] Jakob[12] has described two cases of Simmonds's disease where a careful histological examination of the brain failed to reveal any signs of the pathological changes of presbyophrenia or Alzheimer's disease, which tends to show a certain independence in the causation of the presenile changes.

The theoretical aspect of pituitary pathology is very controversial and complex and cannot be gone into here. Three separate possibilities and their combination seem to form the basis of an attempt to understand and explain the clinical pathology of the pituitary disorders: (1) The impairment of independent glandular activity of the pituitary gland, considered as a whole or in its parts—i.e., of anterior, posterior, and intermediate lobe. The anatomical and physiological existence of the last-named in man is doubtful and controversial. (2) The correlation and interaction of the effective pituitary gland within the system of glands of internal secretion. (3) The relation of the disease to the subthalamic centres in the mid-brain.

Several authors, like Biedl, Cushing, and others, hold that there is a close relationship between Simmonds's disease and the syndrome first described by the French as "insuffisance pluriglandulaire." Good therapeutic results from the ingestion of anterior-lobe preparations are claimed by Reye, Nonne, Lichtwitz, and others. Amongst the numerous contributions to the literature of the subject may be mentioned certain papers to which reference is made in the bibliography.[13-25]

FIG. 1.



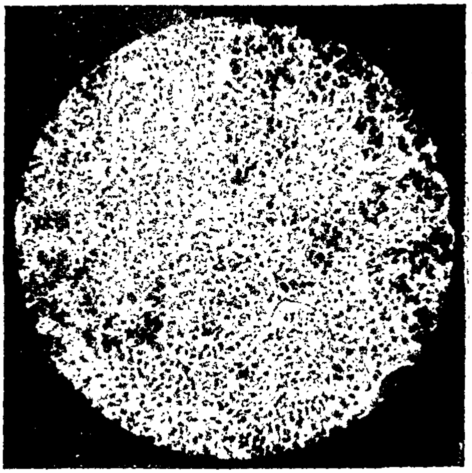
Section of anterior lobe of pituitary gland, showing fibrotic atrophy. Hæmatoxylin-eosin stain.

Report of Case.

A woman of 37 was admitted from Woodstock Workhouse Infirmary on Oct. 23rd, 1922. She was moody, sullen, and quarrelsome, threatened to "finish herself," got out of bed at night, and tried to get at the knives. She was stated to have been feeble-minded to a moderate degree since childhood and to have had illegitimate children. She became a charge to the workhouse. The family history was unobtainable. There was no history of miscarriages. At the time of admission no marked pathological changes were found in the internal organs. There was a slight parenchymatous struma and double optic atrophy. Both knee-jerks were absent and both ankle-jerks present. There was no light reaction in the pupils, and the Wassermann reaction was positive.

The depression seemed to clear up, and the patient became orientated and quiet, and her bodily condition improved.

FIG. 2.



Section of anterior lobe of pituitary gland of an abortive case of dystrophia adiposo-genitalis (Fröhlich's disease) with well-developed glandular tissue. Hæmatoxylin-eosin stain.

On March 23rd, 1924, she was discharged to the workhouse, whence she was readmitted on August 10th, 1927. She was then bedridden, and had apparently been very restless for some time. She said that "strong feelings came over her, and then for a time she did not know where she was," "that she intended to make away with herself." She had bedsores on the buttocks and a small abrasion on the outer aspect of the left knee. The knee- and ankle-jerks were absent, but there was no Babinski sign. There was marked ataxia. The globulin in the cerebro-spinal fluid, tested by Pandy's method, was + +, and the Lange gold-sol reaction gave a tabetic curve. She had shooting pains and gastric crises with repeated vomiting only relieved by morphia. She was very restless and agitated at times, and had persistent constipation. On Nov. 4th, 1927, she was inoculated with malaria by mosquitoes. On Nov. 19th she had her first rigor, and her temperature went up to 104° F. The second rigor was on Nov. 21st, when the temperature rose to 105° F. On Nov. 23rd she was given quinine, as her condition was not favourable to more rigors, and no more occurred. On March 26th, 1928, she showed no physical inprovement, had a series of abscesses on the buttocks, and was mentally very lethargic. A month later she was very emaciated and showed a progressive loss of hair from her head. She had an almost voracious appetite. On May 21st a perforating ulcer had developed on the right hip; on account of her extreme emaciation the capsule of the joint was exposed to view. There was also an ulcer on the left hip. On June 2nd she was weaker and incontinent, and on June 7th, at 3.55 A.M., she died.

Post-mortem Report.

Extreme emaciation. No external injuries. Perforating bedsores at both trochanters and along the proximal part of the pelvis. Skull symmetrical, eburnation of diploë, diameter about 8 mm. Almost complete ossification of sutures. Adhesion of dura mater to skull-cap. Pia-arachnoid thickened, adherent to convolutions. Convolutions flat, sulci shallow, more marked in fronto-parietal region. Consistence of brain and spinal cord softened, paste-like. Degeneration of posterior columns in spinal cord from beginning of sacral segments to lower cervical segments. Microscopically, besides loss of medullated fibres in posterior root-zones, marked endarteritis luetica throughout the central nervous system.

Adhesions at both pulmonary apices. Acute inflammatory process on the left lower lobe of the lungs with marked œdema. Heart not enlarged, tricuspid and mitral valve show some fibrotic changes, possibly of syphilitic origin. Several atheromatose plaques and one scar about 4 mm. in length in the arch of the aorta. Sclerotic changes in both coronary arteries. Fatty degeneration and partial atrophic changes in the liver. Gall-bladder normal. Bile-ducts patent. Atrophic changes in the mucous membrane of the stomach and intestine. Parenchymatous nephritis. Spleen slate-grey with perisplenitis, showing Malpighian corpuscles and increase of trabeculæ on cross-section; slightly enlarged. Pancreas and suprarenal bodies without marked changes. Parenchymatous struma to a moderate degree. Retrogressive changes of uterus and ovaries. Anterior lobe of pituitary gland (Fig. 1): very extensive fibrosis with consecutive reduction of glandular tissue to small irregularly scattered islets. Almost complete disappearance of eosinophil cells, basophil cells slightly increased, some "main" cells well preserved. Almost complete disappearance of vessels. Absence of colloid cysts in pars intermedia.

Posterior lobe: Apart from a slight gliosis and reduction in size, no pathological changes seen. Capsule irregularly thickened. Fig. 2 shows a well-developed anterior lobe for comparison.

Oppenheim mentions in his "Text-book of Nervous Diseases" (1913, vol. i., p. 186) that he saw two cases of tabes dorsalis in which, besides a local muscular atrophy, a striking general marastic (cachectic) condition was a feature, and adds that he feels justified in supposing, from his own experience, that general emaciation may be a symptom of the disease, that a rare form ("marantic tabes") exists which is characterised by an early, considerable general emaciation; he adds an illustration of one of his cases (Fig. 184). A spontaneous loss of teeth without caries in tabes dorsalis is also described in the same text-book (p. 181).

We venture to suggest that these are pituitary symptoms in the meaning of Simmonds's disease.

Summary.

The case considered on the whole shows a fairly typical course of tabes dorsalis. Within about three months of the patient's death rapid emaciation set in, which was *accounted for at the post-mortem* examination by a fibrous atrophy of the anterior lobe of the pituitary gland—Simmonds's disease. It is not unlikely that when more attention is directed to the possibility of this condition a greater number of cases will be clinically diagnosed. Attempts at organotherapeutic treatment seem to be indicated.

DIGESTIVE ENZYMES OF THE HUMAN FŒTUS.

BY M. F. LUCAS KEENE, M.B., B.S. LOND.,
PROFESSOR OF ANATOMY AT THE LONDON (ROYAL FREE HOSPITAL) SCHOOL OF MEDICINE FOR WOMEN;
AND
E. E. HEWER, D.Sc.,
LECTURER IN HISTOLOGY AND ASSISTANT LECTURER IN PHYSIOLOGY AT THE SAME SCHOOL.

MANY observations have been made at various times upon the external secretions of the human fœtus, and the time of the first appearance of the different digestive enzymes is very variously quoted by different investigators,[1,2] many of whom have reported upon a few specimens only. As this problem is peculiarly one in which varying external conditions may vitiate the finding, the resulting experimental error in observation can be eliminated only by examining a very large series of cases under conditions as constant as possible. The present paper is based on the examination of 39 fœtuses, admittedly a small number, but dependable because only absolutely fresh material was used. The fœtus was considered as fresh only when received within 12 hours of birth, when it had died during or after parturition and not previously, and when on post-mortem examination it showed no autolytic change. Unfortunately no material suitable for enzyme-testing was obtained earlier than the sixteenth week, so that these observations extend only over the period from 16 weeks to full time.

Methods.

Histological.—*Material was fixed either in formalin* (5–10 per cent. in NSS), or formo-acetic Muller (formalin 5, glacial acetic acid 5, Muller's fluid 90), and embedded in paraffin wax. Sections were stained by Scott's hæmatoxylin and Biebrich scarlet, by Mallory's aniline blue-orange G mixture, and by Weigert's resorcin-fuchsin method. The sections were mounted in Gurr's neutral mounting medium or Canada balsam.

Chemical.—The fresh organ was quickly washed free from blood, chopped up finely, and extracted in about 10–15 times its volume of 90 per cent. glycerine in an incubator at 37° C. for 12 hours. The extracts were then filtered and tests were performed for various enzymes as follows. The quantities given represent the proportions and not necessarily the actual amounts used.

(*a*) *Amylase* (salivary and pancreatic). 1 c.cm. of 1 per cent. starch solution + 1 c.cm. extract (submaxillary or pancreas) + a trace of 1 per cent. sodium carbonate. Incubate at least two hours. Test with weak iodine for erythrodextrin.

(*b*) *Pepsin.* 1 c.cm. of 0·2 per cent. hydrochloric acid + 1 c.cm. extract (stomach) + washed fibrin. Incubate at least two hours; boil; filter. Test filtrate by xanthoproteic or Biuret test for proteoses.

(*c*) *Rennin.* 1 c.cm. milk that has been just brought to boiling-point and then cooled + 1 c.cm. extract (stomach) + trace of hydrochloric acid. Incubate at least one hour. Examine *for formation of curd.*

(*d*) *Trypsin.* Test as for pepsin, but using pancreas extract and adding 1 c.cm. K_2HPO_4 solution[3] instead of hydrochloric acid.

(*e*) *Erepsin.* Test as for trypsin but using duodenal extract.

(*f*) *Lipase.* 1 c.cm. of boiled milk + ½ c.cm. of 2 per cent. bile-salt solution, + 1 drop phenolphthalein, + 1 c.cm. extract (pancreas) + enough 1 per cent. sodium carbonate to render pink. Incubate at least two hours. Examine for neutralisation of alkali as shown by loss of colour.

(*g*) *Lactase.* 1 c.cm. of 1 per cent. lactose, + 1 c.cm. extract (duodenum). Incubate at least two hours. Test for glucose by Barfoed's test.

(*h*) *Invertase.* 1 c.cm. of 1 per cent. cane-sugar, + 1 c.cm. extract (duodenum). Incubate at least two hours. Test for glucose by Benedict's test.

---

[1] Feldman, W. M.: Antenatal and Postnatal Child Physiology, 1920, pp. 178–185.

[2] Hammar, J. A.: Uppsala läkareförenings förhandlingar, n.f., 1925, xxx., 151.

[3] Cole, S. W.: Practical Physiological Chemistry, Cambridge 1926, p. 28. Series C. pH = 7·9.

(*i*) *Maltase.* 1 c.cm. of 1 per cent. maltose + 1 c.cm. extract (duodenum). Incubate at least two hours. Test for glucose by Barfoed's test.

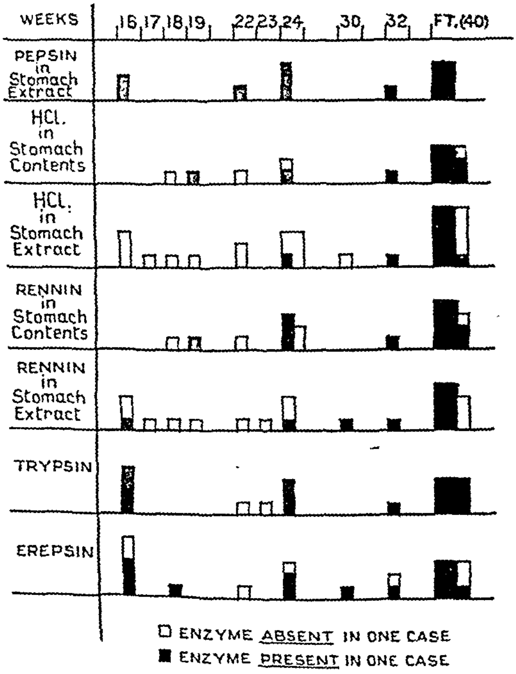
In every case a control experiment was carried out, the organ extract being first boiled. In addition, hydrochloric acid was tested for by Günzberg's test. Some tests were carried out for the presence of enterokinase and trypsinogen, but the method appeared to us open to criticism, and the results are not here recorded. In a few cases the contents of the stomach were pipetted off and tested separately, an extract being subsequently made of the washed gland, and also tested.[4]

Salivary Glands, Stomach, and Small Intestine.

Ptyalin (salivary amylase) was tested for in 19 cases, from 17 weeks upwards; its presence was detected in 5 only out of 12 full-time fœtuses. No trace was found in earlier extracts (see Chart 2). No chemical tests were carried out for the other constituents of saliva, but from the microscopic structure of the glands mucin was probably present. Definite mucin-secreting cells are found at 24 weeks, and the ducts contain a basophil mucin-like material. Previous to this (16 weeks) a similar material is seen in the lumen.

Pepsin was found in every case tested—namely, 13—varying from 16 weeks up to full time. Rennin was found in the gastric contents in 18 out of 23 cases, the earliest being 19 weeks. In the extract of the mucous membrane rennin was found in 12 out of 24, once at 16 weeks, and then not until 24 weeks (see Chart 1).

CHART 1.

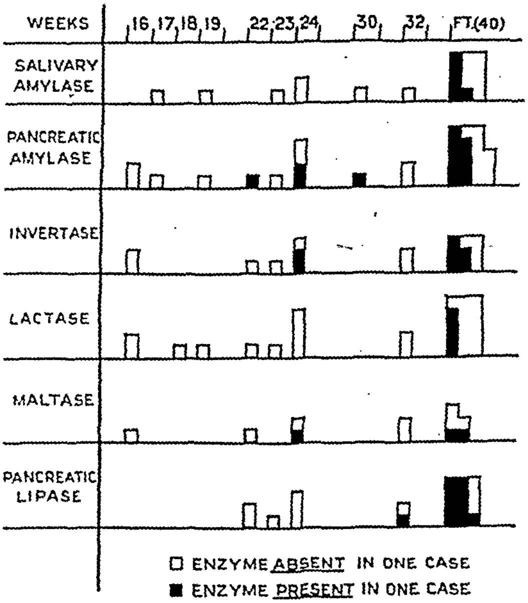


Hydrochloric acid, as tested by Günzberg's reagent, was found in the stomach contents (15 specimens), the earliest at 19 weeks, and eight out of nine times at full time. In the extract hydrochloric acid was not found so early, being present first at 24 weeks (once out of 14 tested up to and including this age); at full time it was found in 11 out of 15 specimens (see Chart 1).

These findings are borne out by the microscopical appearance. Though the gastric glands have begun to develop by the eighth week, differentiation of the cells first occurs at 16 weeks. At this age three types of cells can be clearly distinguished: (*a*) some containing mucin; (*b*) some large oval cells staining red with Biebrich scarlet and lying in the deeper parts of the glands, probably oxyntic cells; (*c*) smaller granular cells in the outer part of the glands, probably peptic cells.

Erepsin was present in extracts of the duodenal wall in 15 out of 22 cases, and was actually found in three out of five specimens of 16 weeks (see Chart 1). The sugar-hydrolysing enzymes were all present at birth, although inconstantly; invertase and maltase were also found at 24 weeks, but not previously (see Chart 2). We think that our failure to detect these ferments at earlier ages may be due to their relative instability. The presence of well-marked goblet cells in both villi and crypts at eight weeks suggests that mucin is probably present at this age, though tests for mucin were not actually made.

CHART 2.



Pancreas and Liver.

Pancreatic amylase was found in extract of pancreas in 13 out of 31 cases, the earliest at 22 weeks, but it is to be noted that it was not present constantly at full time (see Chart 2). Pancreatic lipase (20 cases) was found in 14 specimens, once at 32 weeks. Trypsin (17 cases) was present from 16 weeks, except in two specimens (22–23 weeks) (see Chart 1). The test for trypsinogen and enterokinase was not considered very satisfactory, and the results are therefore not included. Microscopically the islets were first detected at 75 mm. (10–11 weeks). By 12 weeks the islets were well differentiated, and the alveolar cells were strongly eosinophil and granular.

No chemical tests were carried out for the presence of bile-salts or mucin—i.e., the liver secretory products concerned in digestion. The anlage of the gall-bladder was seen in the 10 mm. embryo. Bile-ducts were first clearly seen at 12 weeks.

Discussion.

There are many difficulties in assessing the results of this investigation. There is, in the first place, little or no exact knowledge of the conditions present in the still-born fœtus effecting alteration or even destruction of bodies so unstable as enzymes, though it is known that certain factors are at work. For example, it is known that changes of hydrogen-ion concentration occur rapidly after death, and further, that these variations materially affect the activity of enzymes, but the exact influence of such changes on specific ferments is not known. Just as there are variations in the rate at which post-mortem changes occur in different organs, so also alterations of hydrogen-ion concentration and other post-mortem conditions may effect certain enzymes more rapidly than others, and thus it is probable that a negative finding is of less value than positive evidence.

---

[4] A large number of these tests were kindly carried out for us by Miss D. Woodman, M.Sc.

Following up this line of argument, we submit that the carbohydrate-splitting ferments may be more unstable after death than the proteolytic enzymes, otherwise it is most remarkable that the latter are present as early as 16 weeks, whilst the former are not constantly found even at full time. In addition, contrary to expectation, there is very little correlation between the appearance of pancreatic amylase and intestinal maltase. Hydrochloric acid, though not present as early as pepsin, was fairly constantly found at birth. It is suggested in this connexion that both our own varied results and the inconstant findings of other workers may be due to post-mortem decomposition of the hydrochloric acid, or to vitiation of the Günzberg reaction owing to the presence of mucin.

Summary.

1. Proteolytic ferments present at 16 weeks. 2. Hydrochloric acid present at 19 weeks. 3. Rennin present at 19 weeks. 4. Pancreatic lipase present at 32 weeks. 5. Carbohydrate-splitting ferments found very rarely at 24 weeks and not constantly at full time. [No tests were carried out on material younger than 16 weeks.]

This research is part of a general inquiry into fœtal development, the expenses of which are being met in part by a grant from the Thomas Smythe Hughes Medical Research Fund.

Clinical and Laboratory Notes.

A NOTE ON
BANISTERINE OR HARMINE.

By J. A. Gunn, M.D., D.Sc.,
PROFESSOR OF PHARMACOLOGY IN THE UNIVERSITY OF OXFORD.

About a year ago Lewin [1] published results of an investigation of the actions of *Banisteria caapi* and of the alkaloid banisterine obtained from it. Extracts or decoctions of this plant have been used by natives of South America as a kind of intoxicant. From experiments on laboratory animals and on man, Lewin found that banisterine produced a stimulation of the central nervous system, followed, in the case of larger doses especially, by depression. On the basis of his experiments the alkaloid was tried in post-encephalitic rigidity with results said to be equal, or superior, to those obtained by the use of hyoscine in the same condition. At the end of this investigation Lewin was informed by Merck that the alkaloid banisterine was chemically identical with harmine. Both possess the same formula, $C_{13}H_{12}N_2O$. Lewin was able, from the literature on harmine, to adduce as points of agreement only the heightening of motor excitability up to convulsions, and stated that further experiments were necessary to establish the identity of banisterine and harmine.

At a recent meeting of the Berlin Medical Society, Lewin and Schuster [2] reported the results of the use of banisterine in cases especially of Parkinsonism. In the subsequent discussion Stern mentioned that he had employed harmine in a few cases with success, but Lewin did not admit the identity of action of harmine and banisterine. In a comment on the problem in THE LANCET it was stated that it is essential that a—

> "Pharmacological comparison of banisterine and harmine should be instituted as soon as possible. The point is important, because if Prof. Lewin's results are confirmed a demand may arise for this drug, and harmine can probably be made much more easily from the usual source, the seeds of *Peganum harmala*, than from the plant utilised by Prof. Lewin, *Banisteria caapi*."

Many years ago I carried out a somewhat detailed investigation of the pharmacological actions of the two alkaloids of *Peganum harmala*, harmaline and harmine. As the results of this investigation were published in the *Transactions* of the Royal Society of Edinburgh—a publication which is not usually searched for work of this kind—it is perhaps not surprising that neither Lewin nor anyone as far as I know, who has worked on banisterine or harmine, seems to be acquainted with my papers. As the result of data already to hand, it would seem possible to institute a comparison of banisterine and harmine from the pharmacological viewpoint; indeed, what difficulty there is arises from lack of detailed knowledge of the actions rather of banisterine than of harmine. As I have been investigating during the past year the actions of the nearly related tetrahydroharmine, in the course of which I have repeated many of the experiments with harmine and harmaline, I feel in a favourable position for making a comparison between the actions of banisterine and harmine upon the basis of such knowledge of the two alkaloids as is at present available.

The actions of the alkaloids of *Peganum harmala* were first investigated in 1895 by Tappeiner.[4] He gave a general account of the actions of harmaline—e.g., the motor stimulation of the central nervous system (tremors and convulsions), followed or accompanied by paresis; he described the slowing of the pulse, and he roughly estimated the lethality in laboratory animals. He also made a few experiments with harmine which acted very similarly. His investigation was stated to afford no basis for the therapeutic use of the alkaloids.

Some years later I described in greater detail the actions of harmaline [5] and harmine,[6] as a result of which I came to the conclusion that the actions of these alkaloids generally resemble those of quinine but that, in regard to the stimulation of the central nervous system, their actions resembled those of some of the other cinchona alkaloids rather than of quinine itself. On the basis of these experiments, harmaline and harmine were tried in malaria,[7] with the result that the former was found to have curative results in acute malaria, though inferior to quinine, but harmine gave promising, though (owing to the small number of cases available) not convincing, results in relapsing malaria. Flury [8] also investigated the actions of the harmala alkaloids, with very similar results so far as the nervous system and circulation were concerned.

In regard to my own position, further experience has confirmed my belief that there is a remarkable resemblance in their fundamental actions between the cinchona alkaloids and the harmala alkaloids. This is true, for example, of their actions on protozoa, on voluntary muscle, on the circulation, and on organs containing involuntary muscle—e.g., the uterus, spleen, intestine, blood-vessels. Unfortunately, no sufficiently detailed examination of such actions of banisterine has yet been done, but I should suggest to those who can obtain banisterine for investigation that if the latter possesses the following actions it would go far to establish the pharmacological identity of this alkaloid with harmine: produces contracture and inexcitability of frog's muscle in a concentration of 1 in 5000 or greater; contracts frog's blood-vessels; contracts the rabbit's uterus in concentrations of 1 in 20,000 or greater; relaxes the spleen and intestine; has a powerful toxic action on protozoa. If banisterine proves identical with harmine these actions will have to be kept in mind in its therapeutic employment.

In the absence, however, of detailed information of the pharmacological actions of banisterine, it is, I think, still possible to institute a useful comparison between the actions of the two alkaloids. In attempting to do this, I propose to direct special attention to their actions on the central nervous system, seeing that it is for this use that banisterine has so recently acquired its reputation.

It is in the first place interesting that both plants sources have been used to form a kind of intoxicant. Lewin has given an interesting account of this use of *Banisteria caapi*. I drew attention to the use of harmala seeds as an intoxicant in North Africa, with the comment[7]: "It is possible that in large doses it (harmine) will produce a kind of intoxication in man, seeing that it has been found to produce a pronounced stimulation of the cerebrum in the lower animals." Vertigo and nausea and slowing of the pulse are described as symptoms occurring in man with banisterine, and they occur also with the harmala alkaloids.

In laboratory animals, the action of the two alkaloids can be more easily compared. Lewin gives the minimal lethal dose of banisterine for guinea-pigs as 0·1 g. per kg., practically identical with what I found for harmine—viz., 0·12 g. per kg. In the rabbit he found banisterine caused death in a dose of 0·2 g. per kg. in 3–6 hours, while I found death from 0·23 g. per kg. of harmine in 2 hours 40 minutes. So far as lethality goes, the results are sufficiently near to allow the alkaloids being identical.

Lewin describes the symptoms produced in the rabbit by banisterine, and the closeness of the resemblance between that description and the effects of harmine in the rabbit as I described them is remarkable, as the following extracts will show.

Banisterine (Lewin).—Two minutes after injection the whole body trembled, the fore limbs were kept stretched in front. After seven minutes, short-lasting rotation movements round the long axis of the body followed. The animal lay down and made drum-beating movements with the fore limbs. (This was followed by a condition of stupor.)

Harmine (Gunn).—Five minutes after injection there were marked tremors of the head and fore part of the body and the hind limbs were extended so that the abdomen touched the ground. After 12 minutes a slight epileptiform convulsion occurred, after which the animal lay quiet. A similar but more violent convulsion occurred later during which the animal fell on its side and rolled over sideways two or three times. After this the rabbit lay on its side with feeble pawing movements of the limbs. (This was followed by a condition of motor paresis.) Considering that the dosage was different, the qualitative resemblance in the symptoms selected for mention is at least very striking.

No one could read the descriptions of the effects of the two alkaloids without being impressed by the resemblance. The chief symptoms produced by both are tremor and swaying of the body, with impulse to continual movement, especially "running" movements or "drum-beating" movements of the fore limbs. The tremor is aggravated by voluntary effort. With the related alkaloid harmaline I deduced from the symptoms the occurrence of hallucinations in cats, just as Lewin did with banisterine in dogs. So far as mammals are concerned it would seem impossible, on the present data available, to distinguish the actions of the alkaloids. Harmine produces slightly different symptoms in different species of mammals. A more exact comparison could be made by comparing parallel doses of the two alkaloids in different species of animals. The lethality of harmine for several species of animals has already been determined.[6]

The only apparent discrepancy is in regard to the frog. In a very brief account, Lewin describes a persistent heightened reflex excitability followed by paralysis of the extremities. The animal assumes a peculiar attitude in which the head is immovable as if in long-lasting opisthotonus, a posture which is not altered by death. On the other hand, I found no convulsive symptoms with harmine in frogs, but only paralysis of lower motor centres. Flury likewise found no convulsive symptoms with harmine. I did, however, point out the rigidity of the back muscles, ascribing it, I think rightly, to the local action of the injection into the dorsal lymph sac. I had found that solutions so low as 1 in 5000 produced rigid contracture of frog's voluntary muscles, and the hypodermic injection being much more concentrated very markedly produced this effect on the muscles of the back. Unfortunately no data are available in regard to the action of banisterine on frog's muscle. It appears to me, however, that Lewin may have confused such an action with a strychnine-like opisthotonus. Indeed, the fact that the posture was unaltered after death renders this local action almost certain.

Perhaps these points may suffice for the present to emphasise the extraordinary close resemblance between the pharmacological actions of banisterine and harmine. If the alkaloids prove to be identical, the fact does not of course detract from Lewin's initiative in being the first to employ banisterine in paralysis. Having exhausted my supply of harmine, I have not been able to try it in post-encephalitic conditions but I hope soon to have an opportunity of doing so. If harmine, whether identical with banisterine or not, proves of value in nervous diseases, the question will arise whether any of the allied alkaloids may not be even better. It is difficult to prophecy in view of the fact that the exact cause of the rigidity in Parkinsonism is not determined. If the beneficial effect is due to a stimulant action then harmine will possibly be superior to harmaline and possibly inferior to apoharmine. I hope to publish very soon a detailed account of the action of tetrahydroharmine.

THE PRESERVATION OF ANÆSTHETIC ETHER.

BY C. LANGTON HEWER, M.B., B.S. LOND.,
ANÆSTHETIST AND DEMONSTRATOR OF ANÆSTHETICS,
ST. BARTHOLOMEW'S HOSPITAL, LONDON.

IT has been recognised for many years that anæsthetic ether, when stored, tends to oxidise and that peroxides, aldehydes, and other substances make their appearance. Furthermore, these decomposition products have been shown to be toxic and some even think that "ether convulsions" are due to their presence.[1] Organic chemists have done a great deal of work in trying to find means of checking this decomposition and their efforts have met with a large measure of success. In 1921 it was shown that carbon dioxide had a stabilising effect upon ether,[2] and many manufacturers both in this country and in the United States now treat their product in this way before it is bottled. Strong light and heat have also been shown to favour decomposition, and most ether is now put up in dark amber-coloured bottles with instructions for storing in a cool place.

Anticatalysts.

In spite of these precautions, however, ether still tends to oxidise when kept for prolonged periods, and efforts have been made to find a suitable anticatalyst which will inhibit this action. The addition of a small quantity of alcohol has been tried,[3] but this was not so successful as it was in the case of preserving chloroform. Metallic mercury has a slight but definite anticatalytic action, the most efficient form being that of "grey powder" which has a larger effective surface than the equivalent amount of metal in the form of a globule. It has recently been shown, however, that copper is a most excellent anticatalyst and that ether stored in copper cans shows no tendency to decompose even in the most adverse circumstances.[4] It seems probable, therefore, that the storage problem is solved, and that in the near future ether will be put up in containers which are internally copper-plated.

The next difficulty to be overcome is the decomposition of ether through which gases are bubbled. At the present time many types of anæsthetic apparatus exist in which air, oxygen, or nitrous oxide and oxygen are passed over or through ether, and it is notorious that oxidation occurs very quickly under these conditions. Dr. C. F. Hadfield investigated the contents of the ether bottle of a sight-feed apparatus through which nitrous oxide and oxygen had been passed.[5] He found that decomposition varied with different ethers and was accelerated by heating the bottle. Furthermore, the figures for the aldehyde and peroxide contents showed marked correspondence. It occurred to me that it might be possible to utilise the anticatalytic property of copper already referred to, and thus inhibit the oxidation brought about by the passage of gases through ether.

Author's Experiments.

Accordingly, a polished copper plate about 8 cm. long and 3 cm. wide, giving an effective surface of about 48 sq. cm. was placed in the standard ether bottle of a Boyle's apparatus. Approximately one-third of the surface of the copper was above the ether level. This latter was kept fairly constant by the addition of fluid at frequent intervals. The ether used was the purest standard product obtainable, and nitrous oxide and oxygen in the proportion of 5 to 1 were bubbled through it for varying periods. The ether bottle was surrounded by a jacket containing water at room temperature and was exposed throughout to a strong artificial light. The experiments were then repeated without the copper plate and the various samples were analysed with the following results:—

Time of bubbling $N_2O + O_2$ in minutes.	Ether peroxide (parts per million).	
	Without copper.	*With* copper.
0 (control) ..	Less than 0·05	
30	2·5	1·2
60	2·2	0·2
90	1·0	0·5
	Aldehyde (parts per million).	
0 (control) ..	1·0	
30	9·5	2·5
60	11·5	2·5
90	4·0	1·5

This appeared to show that a copper plate does materially diminish oxidation, and it was next decided to find out whether the actual tube which dipped into the ether could be made of copper and produce similar effects. A copper sheath 5 cm. long was therefore made and fitted over the end of the bubbling tube. On repeating the analyses, however, it was found that the rate of oxidation was not changed from that of a standard control. This negative result was thought to be due to an insufficient area of copper above the ether level and another tube 9 cm. long was made giving a total effective surface of about 56 sq. cm., of which about one-third was above the ether level. The series of experiments was then repeated, the analyses reading as follow:—

Time of bubbling $N_2O + O_2$ in minutes.	Ether peroxide.	Aldehyde.
	Parts per million.	
0 (control) ..	0·05	1·5
30	0·05	2·0
60	0·05	5·0
90	0·05	5·0

These results show that practically no oxidation had occurred and that the previous supposition was correct in that an adequate surface of copper must be present above the ether level to secure the best results.

In studying these analyses it may be noticed that in some cases the amount of impurities found after 90 minutes passage of gases is less than that after 60 minutes. This curious result was also observed in the similar but much slower oxidation which occurs with stored ether.[4] It is found that ether kept for two years usually contains less aldehyde and peroxide than that stored for only six months. The probable explanation is that further decomposition takes place and that traces of organic acids are left as the end-product of the reaction.

Conclusions.

1. Pure ether treated with carbon dioxide and stored in copper containers will keep pure almost indefinitely.
2. If anæsthetic gases are bubbled through ether for prolonged periods the rate of decomposition will be greatly diminished if there is an adequate area of copper above and below the ether level.

My thanks are due to Mr. F. H. Carr, F.I.C., who arranged for the chemical part of this investigation to be carried out at the British Drug Houses Analytical Laboratories.

NOTE ON THE

INHIBITORY EFFECT OF A STAPHYLOCOCCUS ANTIVIRUS IN RELATION TO THE pH OF THE MEDIUM.

BY R. F. HUNWICKE, B.SC. LOND., A.I.C.,
BACTERIOLOGIST, GLAXO RESEARCH LABORATORY, LONDON.

Louros and Gaessler (*Klin. Woch.*, 1927, vi., 1662) have stated that the inhibitory effect of a streptococcus antivirus is due merely to the development of acidity in the medium. They found that the filtered broth culture of a streptococcus had a hydrogen-ion concentration corresponding to a pH of 5·0 to 5·8, and point out that streptococci cannot in any case live in this medium because of its high acidity. Further, they found that streptococci would grow in the filtered broth as soon as it was neutralised with a phosphate buffer solution. They therefore question the existence of a streptococcus antivirus. The following experiment shows that the conclusions of Louros and Gaessler do not hold in the case of a staphylococcus antivirus.

A 500 c.cm. flask of ordinary peptone broth, standarised colorimetrically to a pH of 7·8, was inoculated with a mixed culture of eight strains of staphylococci which had been isolated from the pus of various lesions. The flask was incubated at 37° C. for 36 days. The culture was then filtered through a Berkefeld filter and the filtrate was reinoculated with the same mixed culture of staphylococci and incubated at 37° C. Slight initial growth occurred, but it did not increase macroscopically after 48 hours. The incubation was continued for 17 days, and the culture was then filtered through a Berkefeld filter. The pH of the filtrate was determined electrometrically and found to be 8·6 (two determinations).

To 10 c.cm. of sterile filtrate was added one loopful of pus from which staphylococci had previously been isolated. No trace of growth occurred. In a control broth, similarly inoculated with pus, there was abundant growth of staphylococci.

Further experiments have shown that final sterilisation of the filtrate by steam on three successive days has no effect either on the hydrogen-ion concentration or on the inhibitory power of the filtrate. In one such experiment the pH of the heat-sterilised filtrate was found to be 8·1. Ten cubic centimetres of this filtrate when inoculated with one loopful of a young mixed culture of staphylococci showed only a trace of initial growth, which ceased after 24 hours' incubation.

It is evident, therefore, that the inhibitory effect of a filtered broth culture of staphylococci is not due to the development of acidity in the medium.

Medical Societies.

MEDICAL SOCIETY FOR THE STUDY OF VENEREAL DISEASES.

AT a meeting of this Society on April 5th Dr. F. J. COUTTS, the President, took the chair and a discussion on

VENEREAL DISEASE IN THE MERCANTILE MARINE

was opened by Dr. H. M. HANSCHELL. His experience, he said, had left with him the deep impression that the seafarer, sailing in and out of the Port of London, was anxious to secure expert medical advice and treatment for his venereal disease, and without loss of time. In the sailor these diseases differed in no particular from those of the landsman. The latter had attended in considerable numbers at the clinic which he had had charge of for ten years, and therefore he was in a position to make comparisons. He had had under care for these diseases about 7000 male patients of every nationality, creed, and shade of colour. The recently noted decrease in the incidence of primary and secondary syphilis applied to both seamen and landsmen. More than half the white seafaring men patients he saw acquired their infection in England, and for the most part in London. Most of them got it from prostitutes whom they paid, as also did the majority infected at ports abroad. An increasing proportion of men, he found, sought advice because they feared an unhappy result from their last coitus; of 700 white seamen so attending 124 were found not to have venereal disease. The ages of the infected seamen he saw ranged from 18 to 27. In his last 700 consecutive white cases 10 were infected in North America, 32 in Australasia, 52 in South America, 83 in the Far East. Liverpool figures would probably show different proportions. Of the last 900 consecutive seamen he had seen, 200 were either Asiatics or negroes. Venereal diseases were carried from country to country far more by passengers than by those who worked the ships, and it was not so easy for the latter to hide their disease. Examination of passengers had not yet been extended to include the genitalia, but crews for ships in British ports had to pass a medical examination before they could sign on for another voyage. The majority of seamen in this country were so examined two or three times a year. Stewardesses were medically examined, but not their genitalia. Doubtful cases found during the ordinary medical examination were sent to the clinic, but many of these turned out not to be venereal disease, and though there had been delay in reaching the diagnosis so that a man lost his chance of signing on a ship, no complaint was made. The man was given a certificate to this effect, and this absolved him from a further examination. Dr. Hanschell suggested that some such close working connexion between the venereal diseases clinic and the medical examination of the crews before signing on was necessary; the clinic should be near where the signing on took place, and should not be restricted as to hours. Sometimes disease became manifest on the voyage though it had not been detected at the medical examination.

There was considerable variation, said Dr. Hanschell, in the equipment and capacity of ships' surgeons. Some had not had any first-hand experience in the modern technique of diagnosis and treatment of venereal disease, and comparatively few ships carried proper irrigation apparatus, or such drugs as salvarsan and bismuth. This was a reflection of the neglect of adequate teaching on the subject in the medical schools, but improvement in this respect was now evident, and it was not so seldom that patients came to the clinic armed with careful notes of their case. He believed that most steamship lines had a waiting-list of applications for the post of surgeon, and it would be easy to insist that applicants should produce evidence of capacity to diagnose and treat these diseases by modern methods. Clinics had had an educative effect on even lay members of the crew, and when no surgeon was on board it was clear that treatment was conducted on sound lines. When on shore the men did not delay in seeking advice. Seamen suffering from these diseases did not wish to go home; they asked to be treated at hospital. And they were becoming more fastidiously conscious of their responsibility for the spread of venereal disease. He pleaded for a better education of ships' surgeons in this matter, and more modern and adequate equipment. The great aim should be to prevent cases of venereal disease going on board ship.

Dr. A. O. ROSS (Liverpool) drew a vivid picture of the relaxations awaiting the returning seaman at the ports, conspicuous among which were the opportunities, especially when in drink, of promiscuous sexual congress. Few seamen, he found, continued the treatment until they were cured; some were even too lazy to read the instructions. Institutes existed at Liverpool which catered for the men's amusement and many efforts were made on their behalf. He criticised the poor accommodation for the crews on many ships, even important ones, remarking that several foreign countries set Britain a good example in this regard. He had come to the conclusion that until there was better discipline and the men were provided with more generous accommodation on board ship a serious incidence of venereal disease would continue. In a large series of cases Dr. Ross said his proportions for the different venereal diseases worked out as follows: gonorrhœa, 61 per cent.; syphilis, 29 per cent.; chancroid, 10 per cent. He added that 15 per cent. of the patients at his seamen's clinic were Liverpool townspeople, who found it more convenient to go there than to attend clinics nearer home. South American ports he stigmatised as plague spots in regard to venereal disease, the cases coming from them grossly exceeding (taking into consideration the tonnage concerned) those from any other part of the world. On the other hand, he had high praise for the efficiency of the treatment carried out at Singapore. Of 3000 cases in his clinic 18 per cent. were foreign. Acute cases he persuaded to sign off their ship. Chronic cases were allowed to sail again under promise to renew treatment on their return. For gonorrhœa he thought adequate treatment could only be assured with certainty ashore. Many seafaring men did not regard this disease with any particular seriousness; some indeed were contemptuous about it.

Discussion.

Dr. H. WANSEY BAYLY said most seafarers were of the virile type, who would not be dissuaded from satisfying their sexual instinct, hence prevention should be concentrated upon by giving instructions as to cleanliness and disinfection when risk had been encountered. Measures of this kind in certain ships of the Navy had proved most effectual.

Dr. M. T. MORGAN spoke of the work of a committee of the Board of Trade in the direction of revising the scales of drugs and medical appliances to be carried by various classes of ships. Similar attention had been paid to the medical guide for captains whose ships did not carry a surgeon; and the next subject to which the committee would direct its attention would be the scales for ships carrying a surgeon.

Mr. J. F. PEART referred to the great value of the treatment of gonorrhœa by argyrol.

Dr. JOHN ADAMS spoke of the rarity of cases of chancroid in London nowadays as compared with 40 years ago. He considered that very often surgeons on board ship were inadequately trained for dealing with cases of venereal disease, and insufficiently equipped. There should be a more thorough training of medical men attending clinics for instruction; they should actually do the injections under expert supervision, in order to gain confidence.

Colonel L. W. HARRISON said that the papers by Dr. Hanschell and Dr. Ross, as also remarks by Dr. Adams, confirmed the opinion which he had held for a long time that the regular treatment of a man of the mercantile marine suffering from venereal disease could be secured only by his remaining ashore. It seemed rather hard that a seaman should have to remain ashore so long, and he thought the remedy lay not only in ships being better equipped in material for the modern treatment of venereal disease, but in ships' doctors being better trained to use this equipment. Whatever might be thought about the practicability of continuing afloat treatment commenced ashore, there was no escaping the necessity of accurate diagnosis and skilled treatment of men whose disease began on the voyage. His own experience led him to believe that this was by no means always satisfactory, and he could endorse what had been said about the frequency with which sores had been treated with lotio nigra, or other antiseptics, before microscopical diagnosis had been made. He was particularly glad, therefore, to support Dr. Hanschell's suggestion to take advantage of the numbers of candidates for the post of ship's doctor by insisting on these previously undergoing a post-graduate course of instruction in the modern diagnosis and treatment of venereal disease.

Mr. JONES (National Union of Seamen) and Rev. Mr. DEMPSEY (British Sailors Society) urged the need of prevention, and spoke of the provision being made to entertain the men when they came ashore. Mr. Dempsey thought that one of the greatest assets on the part of the medical man encountering these cases was the adoption of that kindly attitude towards the sufferer.

Commander CAVILL (R.N.R.) praised the efforts being made by various societies on behalf of seamen, and said a real need was the education of the public, land as well as seafaring, to the seriousness of these diseases.

The PRESIDENT agreed that centres for the treatment of seamen ought to be quite near the docks, otherwise the proportion coming for treatment would not be satisfactory. Apparently some of the clinics were so well and considerately conducted that the men attended faithfully. He feared there was much truth in the contention that the only way in which to treat sailors in an effective way was to treat them ashore; but he would not like to think that would be so in the future, as he hoped that when the man went back to sea he would be able still to have proper treatment. He hoped a firm stand would be made in the way of ensuring that doctors appointed to ships should be qualified to treat these diseases properly, and have the equipment which would enable them to do this.

Mrs. NEVILLE ROLFE asked what medical provision could be made for the large number of men engaged in the coastwise trade of the country and those in fishing fleets. Both these classes of men were a long time from home and were in the way of acquiring disease in consequence, and she asked how their treatment needs could be at present met in such places as Fowey and Lowestoft. She also asked whether difficulty was experienced in inducing British seamen to go to foreign clinics for treatment.

Dr. HANSCHELL, in the course of his reply, said he did not think the classes of men mentioned by Mrs. Rolfe (in which he included men working the Thames Estuary) received treatment at all. Yet, if the disease were diphtheria instead of syphilis, hospital accommodation would be quickly found for them.

Dr. ROSS also replied. He agreed that the coastwise men were badly treated in regard to venereal disease. There did not seem to be a V.D. clinic for seamen at Bremen, but cases there were passed on by the British Consul to a practitioner who made the necessary injections at a trifling charge beyond the cost of the drugs.

ROYAL SOCIETY OF MEDICINE.

WAR SECTION.

A MEETING of this Section was held on April 8th, with Lieut.-General Sir MATTHEW FELL, the President, in the chair, to discuss

FUNCTIONAL NERVOUS DISORDERS IN THE SERVICES.

Colonel J. C. KENNEDY said the discussion originated in the fact or belief that during the last few years the incidence of hysteria in the Army had been increasing. It was not surprising that many men should have broken down under the strain of their war experiences, but under normal circumstances hysteria was not looked upon as of much importance among disorders of the male. He was sure, however, that in this time of peace, hysteria existed to a quite appreciable extent. In the five years before the war cases of disease of the nervous system were estimated at 5·7 per 1000 strength, in which the figure for hysteria was 0·1, neurasthenia 0·6, and epilepsy 0·9. In 1927, on the other hand, nervous cases amounted to 7·5 per 1000, with hysteria 0·7, neurasthenia 1·4, epilepsy 0·9. Colonel Kennedy analysed 177 cases occurring during the 18 months following Jan. 1st, 1927. In a few the diagnosis was uncertain, the reasons being: (1) that clinical details were lacking, and so the cases had to be excluded; (2) that the men were suspected of malingering; or (3) that there was some associated condition, such as high blood pressure or duodenal ulcer, or a possibility of organic nervous disease such as encephalitis lethargica or disseminated sclerosis. No case should be diagnosed as hysterical when the symptoms were associated with the presence of an organic abnormality. The 154 cases left, out of the 177, when doubtful ones had been excluded, were grouped according to the main clinical symptoms: (*a*) those in which fits or convulsions were the main symptom, of which there were 82; (*b*) those in which tremors or spasms were predominant, 10; (*c*) those presenting paralyses, disturbances of sensation, and aphonia, 19; (*d*) those with mental symptoms (including amnesia) predominating, 43. Patients in the first group were admitted to hospital for observation of a fit, which might be simply an attack of vertigo, a fainting attack, or an epileptiform seizure. There was a high incidence of these cases in the first two years of service, showing that there had probably been some inherent defect in the person. Young adults during a first experience of a hot climate, if subjected to physical or mental stress, especially if associated with over-indulgence in alcohol, might throw epileptiform fits which were indistinguishable from those of true epilepsy. In group (*b*) tremor and spasm, a history of nervous disability in youth or before enlistment was pronounced. In group (*c*) Colonel Kennedy had noted the power of suggestion, several cases of aphonia having occurred in series. The mental group (*d*) constituted nearly one-third of the total number. The illness was characterised by great irritability and loss of self-control, episodic attacks of delirium or frenzy, and exaltation and depression. Somnambulism, hallucinations, double personality, amnesia, and craving for sympathy were also seen. It was not uncommon to get a history of uncontrollable temper, and in two cases chorea had occurred early in life. There was much evidence that the basic factor in hysteria was a constitutional or inherent instability of the nervous system. These cases afforded ample illustration of Babinski's contention that hysteria was the outcome of suggestion, and that it could be cured by counter-suggestion and persuasion. The manner of disposal of the patients was recorded in 151 instances; 113 men were returned to duty and 38 were found unfit for military service. A large proportion of the invalids manifested mental symptoms.

It might not be easy, Colonel Kennedy continued, to differentiate hysteria from malingering, or from organic nervous disease; still more difficult was it to decide whether one was dealing with a reflex nervous disorder, such as might be associated with a wound. Hysteria might be superimposed upon an organic lesion, or upon a toxic condition. In the "Nomenclature of Diseases" of the Royal College of Physicians, which the Army adopted, no name was provided intermediate between neurasthenia and psychasthenia; hence it was difficult to place such psychoneuroses as anxiety, compulsion, and obsessional neuroses. Some of the cases diagnosed as hysteria and included in group (*d*) could be more accurately described as anxiety neuroses. As to the disposal of cases of hysteria, he thought the decision whether a hysterical patient should be retained in the Service or not depended on a collective consideration of the length of service, the evidence of previous history, and the effect of treatment. In cases in which hysterical symptoms developed soon after enlistment and there was a definite previous history of nervous disability, the patient could be of but little use in the Service. The treatment, apart from general considerations of health and the application of electrotherapy, took the form of counter-suggestion or persuasion. A patient who was not easily amenable to persuasion might require a prolonged course of treatment and ceased to be an economical proposition for the Army in peace time. Still, the principle that no man should be discharged from the Service uncured of a curable disability was one which he would like to see carried out. The question of specialist psychotherapeutic treatment was receiving attention. The situation was different in war time, when the whole of the resources of the country were devoted to the maintenance of man-power. The problem remained, in essence, one of eugenics and upbringing.

Rear-Admiral E. T. **MEAGHER** said he was excluding from his discussion occupational neuroses, such as writer's cramp, chorea which might arise as a result of psychic shock, and exophthalmic goitre. People fell into three groups—normal, psychopathic, and neuropathic. Some held that there was a germinal defect, and that the majority of people who subsequently developed mental defect or disorder had this deficiency. A terrifying shock might have a more or less permanent effect on the mind of a child, but unless neuropathic or psychopathic, such a person was not likely to develop a psychoneurosis. He did not know any way of determining whether such inherent weakness existed in a particular individual. He thought a new entrant to the Service should be under observation in the first months to see whether he manifested any characteristics indicating nervous instability. It was agreed that, apart from hereditary predisposition, a normal person if subjected to exceptional stress might break down. Conditions in the Navy tended to raise the resistance to hysteria. Hysterical manifestations could often be traced to some psychic shock. In the Navy the hysterical fit was common, and for these cases a word or two of advice and discharge to duty was the best course to adopt. Hysteria was manifested most in the less educated; indeed, he had not seen a case of pure hysteria in an officer. It was easily provoked in those of neuropathic constitution.

In regard to diagnosis, the chief thing was to make sure that organic disease did not coexist. According to Kraepelin, 50 per cent. of cases of manic-depressive insanity showed hysteria. In treatment the medical officer should adopt measures to check loss of emotional control by advice or by isolating the patient. Galvanism would cure aphonia, and the hysterical fit could be cut short by physical measures. The doctor must gain domination over the patient. It had been found that the "Old Contemptibles" were not liable to displays of functional nervous disorder. The Navy did not show much change in the incidence of functional nervous disease as compared with the years before the late war. In conclusion, the speaker advocated uniformity of nomenclature and terminology for all the Services and for general use.

Squadron-Leader M. L. **BURTON** said the problems in the Royal Air Force differed somewhat from those in the Army and the Navy, for in peace time the stresses in flying were more pronounced than in those other branches. Even the more stable type of man might break down if the stress was exceptional. The highest figures for the incidence of functional nerve disease in the Air Force were in 1922–23; since then there had been a steady decrease. The incidence was highest among those actually flying; those who through age or other cause did not fly regularly came off best. In neurasthenia the predominant symptom was mental or physical fatigue, with pains, headaches, digestive disturbance, with general depression and lack of energy. In the anxiety neurosis the symptoms were mainly psychic, and the picture was one of nervousness, the patient had a sense of foreboding, worried over trifles, and was easily disturbed. Psychasthenia was characterised by a defective power of volition; the patient was unable to make and act on decisions; doubting mania also occurred, and claustrophobia. Only a small number of flying officers broke down, even when subjected to exceptional stress. Psychoneurosis developed because the subject could not adapt himself to his environmental condition. Some cases of functional nervous disorder occurred after mild head injury, which might have been so slight that concussion was not suspected. When a toxic factor had been operative the case would usually respond to appropriate treatment.

Dr. **ALDREN TURNER** spoke of what had been found in officers at the War Office Medical Board. These cases were usually of a special character. Hysteria, as illustrated by the usual stigmata of paralysis, fits, and anæsthesia, was rare. In young officers there had been cases of fits developing under special circumstances of mental strain and over-work, and perhaps to some extent aggravated by personal habits and climatic conditions, as in India, and in these cases the fits usually ceased on the return of the patient to this country. The outstanding functional nervous disorder observed among officers was neurasthenia, using that term in its widest application. For the purposes of description he had made three groups: (1) the more purely debilitated or nervously exhausted cases; (2) those showing evidence of anxiety, accompanied by characteristic physical signs; (3) those with the post-concussional syndrome. In the group characterised by anxiety, causes of a psychological kind played an important part, including distaste for certain duties and disciplines. Thyroid enlargement in these cases was practically unknown, but there was reason to believe there was a disturbance of endocrine function and of the vegetative nervous system. Those who suffered a breakdown during the war were thereby rendered liable to a relapse if strain and stress were renewed.

BRITISH PSYCHOLOGICAL SOCIETY.

The Psychiatric Section of this Society held a joint meeting with the Psychiatry Section of the Royal Society of Medicine on April 9th. The chair was taken by Dr. **EDWARD GLOVER**, President of the former section. A discussion on

THE PSYCHOPATHOLOGY OF ANXIETY

was opened by Dr. **ERNEST JONES**. He said that the term "morbid anxiety" distinguished a collection of phenomena from those grouped under the name of "fear." Two features justifying this distinction were disproportion between the stimulus and the response, and disharmony between bodily and mental manifestations. In pronounced cases, such as claustrophobia in a closed room, these were very marked, but in borderline instances it was difficult to assess "normal" distress. Psycho-analysts had learned to set a very high standard of "normal" bravery, and to maintain that much timidity passing as normal was really neurotic and curable. The anxiety nature of the physical manifestations was often overlooked clinically. Symptoms such as chronic diarrhœa, psychical impotence, sweating, and flatulent dyspepsia were often wrongly interpreted. Bodily manifestations were much more striking in morbid anxiety than in normal fear, and suggested a thwarted instinct. Another well-recognised feature was the internal disharmony among the manifestations themselves. The physical groups did not seem to be constituted for any biological purpose. Mentally there was neither activity nor passivity, but a curious mixture of over-excitation with paralysis. Physically the dissociation might go so far as to produce a mainly monosymptomatic picture. These features strongly suggested a disorder rather than a simple exaggeration of the fear instinct.

The Freudian View of Anxiety.

Freud had, primarily on a physical basis, separated morbid anxiety from the "neurasthenia" group of Hecker and had regarded it as due to undue sexual excitation with deficient opportunity for discharge. The anxiety was found in place of frustrated libido, and the physiological basis was generated from the physiological basis of libido by some unknown process of chemical transformation. Phobias presented the same picture of anxiety appearing as substitute for a thwarted libidinal impulse. Morbid anxiety was a perverted manifestation of the fear instinct which, in neurotic conflicts, had been stimulated to activity as a protection against the threatening libido. It was the ego's fear of the unconscious. Real dread (i.e., fear of real danger) concerned the ego only and had nothing to do with the desires of repressed libido; it was a normal protective mechanism. Nevertheless real dread contained one useless element which closely resembled morbid anxiety. On the affective side there was a state of anxious preparedness and watchfulness, a useful state but useless when—as often—it passed over into terror, which paralysed both body and mind. Even in situations of real danger a state of developed dread was not part of the useful biological mechanism of defence, but an abnormal response akin to the neurotic symptom. Freud had suggested that this developed dread was derived from the narcissistic libido attached to the ego. The anxiety of war shock and probably also that of hypochondria developed in four stages: (1) perception of external danger; (2) normal fear-response of mental alertness and physical preparedness; (3) over-investment of the ego with narcissistic libido as a protective response; and (4) evocation of morbid anxiety on the part of the ego to the excess of narcissistic libido. The last stage was useless and indeed detrimental as far as the external danger was concerned. Obviously uncontrolled libido could be a danger to the ego; there were manifest social risks and unconscious infantile fears were at work. In face of the infantile situation the child had been helpless, alarmed, and at the end of its resources, and its erotic wishes had been impossible to gratify. To the infant strong excitation without relief was tantamount to losing the very capacity for obtaining relief; the most familiar clinical manifestation of this state was the castration complex. The first step in the child's attempt to cope with this state of affairs was the group of reactions later to be called morbid anxiety. The apparent lack of purpose and coördination reminded the observer of the earliest reactions of the infant to distress, and they performed certain functions. Some of them, notably the over-activity of excretory organs, furnished a limited gratification and relieved tension. Others—for example, the respiratory manifestations—called attention to the urgent need for help. In more extreme states a protective paralysis occurred, and the last resort of the child, as of the neurotic, was an artificial inhibition of vital activity, including the disturbing impulses. Freud—and before him Erasmus Darwin—had suggested that many characteristic features of anxiety were copied or even derived from the event of birth. Only careful correlation of the phenomena of birth and of morbid anxiety with the various manifestations of the fear instinct in animals would give final light on the puzzling problem of the relation between external and internal danger, of the conflict between the interests of the individual organism, and the threat provided by the activity of racial impulses.

Anxiety in the Psychoses.

Dr. HENRY YELLOWLEES suggested that Freud meant a totally different thing by "anxiety" from the meaning applied to the term by psychiatrists. Text-books of psychiatry allowed no place to anxiety among the psychoses save in involutional melancholia, in which it almost invariably played a part. Craig and Beaton called agitated melancholia the "associated psychosis" of anxiety. Clinical observation showed that the true psychoses had little or nothing to do with Freud's anxiety state. Freud had described generally increased nervous instability, whereas the true psychotic was remarkably indifferent to stimuli like noise. The anxious patient imagined the worst in any given set of circumstances, and exaggerated possibilities, but no extension of this mechanism would ever produce the delusions of the melancholic, who ignored possibilities. The melancholic, if he could escape for a moment from his delusions, dealt efficiently with real emergencies; the speaker had known a melancholic doctor, who spent his time banging his head against the wall, turn and deal effectively and professionally with a fellow-patient who had an epileptic fit. There was no better aid to differential diagnosis than an air-raid. Freud had spoken of vertigo, digestive disturbances, particularly ravenous hunger, paræsthesia, and phobias as characteristic of the anxiety state; these were not features of melancholia.

Discussion.

Dr. BERNARD HART said that the theory of transference of libido into anxiety was quite intelligible chemically but not as part of a psychological and biological concept. He agreed with Dr. Jones that fear was an integral part of the reaction to danger and that anxiety and dread were identical in their essential mechanism—in both the ego was failing to master the situation—with the one important difference that anxiety was the response to internal stress and real fear or dread to external danger. The essence of the reaction was not so much the protection of the ego as the failure to protect it adequately. Dr. Rickman had spoken in this connexion of the "helpless ego." If the response to external danger were completely reactive there was no fear, and if the response to internal stress were completely reactive there was no anxiety. If dread was not a part of the normal reaction to danger some other factor was required to account for it, but whatever this factor might be it must afflict a very large proportion of the human race, for dread was extremely common. "Ideal" or "fully adaptive" would be a better phrase than "normal." Other exciting causes than narcissistic libido would fit in with the failure of the ego to master danger. In war-neurosis there was anxiety as long as the struggle to keep unpleasant memories out of consciousness was only partially successful; anxiety disappeared when a fairly adequate pathological adaptation–amnesia, existed or when the situation was altered by treatment and the relation of the ego and the partial memories was adjusted. The full picture of anxiety neurosis did not appear in true psychoses because the clinical picture was modified by the peculiarities of the psychosis, but the chief characteristics of morbid anxiety, if defined as apprehension, tension, and unrest, were clearly discernible in psychoses, especially in involutional melancholia and alcoholic psychosis. The other factors mentioned by Dr. Yellowlees were secondary and derivative. Ravenous hunger was certainly not typical of anxiety.

Dr. R. D. GILLESPIE said that certain well-known states of mental unpleasure arose from conflict, but he doubted whether repression or morbid sexual history were essential factors. One form of anxiety was associated with cardiac lesions. It was obviously protective, but there was some evidence that frustrated instincts might produce a number of states, not anxiety alone. He questioned whether the new-born child showed signs of anxiety, though of course it might have shown them before the final "knock-out" of birth. Obstruction of breathing in a young baby produced signs not of anxiety, but of anger. Shakespeare had anticipated both Erasmus Darwin and Freud, when he ascribed the fearlessness of Macduff to the fact that he had been born by Cæsarean section.

Dr. J. A. **Hadfield** said that there were difficulties in the way of ascribing anxiety states to physiological disorders. Patients might suffer and die from severe toxic conditions without manifesting anxiety; others might appear in normal health and vigour and yet have terrible dreads. Although toxic foci might be found in most cases of anxiety it was likely that they would also be found, if sought, in most normal people. A morbid fear might come on in a 'bus and not in a tube or taxi; were we therefore to believe that the toxic condition became active only in Regent-street and not in Leicester-square? Anxiety might often be dispelled by suggestion, but it was hard to see how the toxicity was cured in this way. There was an intimate connexion between adrenalin and anxiety, but to prove this relationship causal it must be shown that injection of adrenalin produced anxiety. He agreed with Dr. Jones that emphasis should be laid on the psychological factor; that anxiety was abnormal under any circumstances, and that it was not a transformation of libido into fear, but he differed in regarding anxiety as due to fear in the ordinary sense and not only to threats to the libido. It often might be due to threats to the sexual libido, as in nightmares, but conflict between egoistic aggressiveness and fear of obliteration was a common cause. Some marked cause of fear in infantile life very constantly turned up in analysis, and might be regarded as a factor predisposing to the attack of fear. Anxiety states were infantile reactions and fear was one of the most constant experiences of childhood. The infant reacted by fear to noise and to the withdrawal of support, and the older child reacted to fear by egoism and amenableness. Any threat to these precipitated anxiety in later life.

Sir **Maurice Craig** pointed out that no disorder consisted of one symptom and that anxiety appeared in many conditions. From the therapeutic standpoint he wanted to know why these factors became effective. Pavlov's work held out a hope that something might be done to prevent their operation.

Dr. W. H. **Stoddart** said that for a long time he had been unable to differentiate between involutional melancholia and the melancholia of manic-depressive insanity because anxiety occurred in both. He had found anxiety states also in paranoia, but did not agree that they were characteristic of all neurosis; some obsessional cases might show no anxiety. He believed the value of potassium bromide to lie in its anaphrodisiac properties.

Dr. **William Brown** pointed out that one-seventh of all men invalided from the army were victims of neurasthenia, despite the fact that 70 per cent. of those who came to special shell-shock centres were fit to be sent back into the line after treatment. He therefore agreed with Dr. Hart in requiring explicit evidence of narcissism as the cause of the neurosis, which must be very common. Fear was the result of failure of adaptation and was distinct from the instinct of self-preservation. He protested against the use of the term "libido" as if it were something that could be repressed and had its own energy.

Dr. L. S. **Kubie** asked whether an anxiety situation would always lead to an anxiety state. The hysteric might have no emotional content, although the origin of his condition lay in a difficult emotional situation often tinged with anxiety. The absence of anxiety from the picture of psychotics still left the problem of what part anxiety might have played in the production of their symptomatology.

Dr. T. A. Ross described a case in which anxiety was manifested without any lack of direct sexual expression. The psycho-analyst might claim that this expression had been absent in early childhood, but the childhood of the patient had offered several far more obvious causes of fear; he had lived in fear of hell inculcated by a religious father and of destitution because his parents were in the habit of leaving him alone in the evenings. Sex differences were to be found everywhere, but these other difficulties were extremely important. The whole life of many children was one of discomfort and fear.

Dr. **Jones**, in reply, agreed that by "normal" he meant "ideal" or "completely adapted," which was very rare indeed. The total figure for shell-shock in the army only worked out at about 2 per cent., which was the figure also given for homosexuality among the general population. He agreed that anxiety might be due to conflict in respect of hatred or aggressiveness, but held that the vast bulk of those emotions were evoked as a result of thwarted libidinal impulses. Why was a patient afraid of his libido? Obviously because of what it might lead to, and murder was one of the most likely things.

Dr. **Yellowlees** also replied.

EDINBURGH OBSTETRICAL SOCIETY.

At a meeting of this Society on March 15th, with Dr. **Haig Ferguson**, the President, in the chair, a paper on

A Scheme of Maternity Service

coördinating antenatal, domiciliary, and hospital treatment was read by Dr. **James Young**. It was now generally agreed, he said, that the high maternal mortality and morbidity rates were dependent primarily on the inadequacy of the machinery of present-day midwifery. The present service by medical men was wasteful of lives and health because the duties of general practice were incompatible with satisfactory midwifery. The annual death-rate amongst mothers in England and Wales was about 5 per 1000 live births. This implied the death of about 3000 women every year and, on a moderate estimate, at least 30,000 more women annually suffered more or less lasting damage from childbearing and childbirth. The best results were found where the service was carried out by midwives with doctors available for the emergencies. The proved advantages of such a combine were seen in the practice of the Queen Victoria Jubilee Institute for Nurses of England and Wales and in the outdoor practice of the large maternity hospitals, where the death-rate was very low. An ideal practice in these respects was the East End Maternity Hospital in London, where for many years the death-rate in a total of about 2000 unselected cases treated annually was under 1 in 1000—that is, about one-fifth of that obtaining over the rest of the community. On analysis the reason for the low death-rate in these hospital practices was found in the fact that they were carried out by self-contained units, each serving its own district, in which the normal cases were conducted physiologically by midwives and in which the antenatal supervision and the management of the abnormal cases were carried out by the doctors belonging to the service. In this way there was a continuity of supervision and control of the antenatal, the domiciliary, and the hospital treatment of the patients and of the personnel responsible for the services. The system made for a physiological management of the 90 per cent. or thereabouts of normal cases and for early discovery and efficient treatment of abnormalities.

Dr. Young believed that an adequate maternity service was possible only if planned on a national basis, having as its object a coördination of the activities of the midwife, the doctor, the National Health Insurance, and the local authorities, which at present were unrelated and often overlapped. This service should work in conjunction with voluntary agencies, such as hospitals, and should include: (1) a midwife for every labouring woman; (2) antenatal supervision of every case; (3) a service by doctors for complications; and (4) the hospital. Pending establishment of a national service much might be done if local authorities undertook to make provision for their own needs. It was important to relieve doctors in busy general practice of the duties of midwifery, and the doctor personnel or the service should consist largely of general practitioners selected because of their special experience and training and of a comparatively small number of specialists. Dr. Young believed that in every area the "unit" system should be aimed at as far as possible for, by ensuring continuity of treatment and responsibility, it would lead reciprocally on the one hand to an elevation in the standard of domiciliary practice and on the other to a prevention of the tragedies of the present-day maternity hospitals. The fact that all cases were under the control of the unit from the beginning meant that there was no vitiation of the hospital environment by the introduction of women with passages infected before admission by the injudicious management of some outside attendant over whose methods the hospital had no control. In this way the atmosphere of the hospital was kept secure for clean midwifery. In the East End Maternity Hospital in London, whose practice was based on this sytem, sepsis had been practically eliminated for many years. On the other hand, infection of the normal case was one of the outstanding disadvantages of the present-day maternity hospitals, which opened their doors to clean and unclean alike. The recent report of the Scottish Board of Health on maternal mortality referred to the high death-rate in maternity institutions in Aberdeen due to this contagion and other writers (for example, Dame Janet Campbell) had referred to the same thing. In the Edinburgh Royal Maternity Hospital there had been 72 cases of puerperal sepsis with five deaths amongst normal spontaneous deliveries in four years. Dr. Young spoke of the complexity of the segregation problems which faced every such mixed hospital and raised the question whether, under the present unsatisfactory conditions of maternity practice, it might not be desirable to abolish the large mixed hospital and, in such districts, to have two kinds of hospital, the one for "booked" and clean cases—that is, those under the supervision of the hospital—and the other for the infected or suspect cases. He believed that the "suspect" case (for example, the unsuccessful forceps case, the case of placenta prævia plugged before admission, and the abortion) raised even greater segregation difficulties than the frankly septic case and that the tragedies of the hospital sprang chiefly from it.

Dr. E. **FARQUHAR MURRAY** (Newcastle) read a complementary paper on

The Future of Obstetrics,

with Special Reference to the Development of a Maternity Service. The main criticism of the present system, he said, was that essential services were not available for many patients of the industrial classes, and he indexed the essential requirements as: (1) Antenatal supervision. (2) Clean surroundings during the confinement which takes place under the supervision of a midwife. Also an abundance of surgical dressings and lotions. (3) A doctor who is on call to assist delivery, to repair lacerations, and to deal with complications. (4) Good nursing. (5) Postnatal supervision. (6) A consultant service. It was absolutely essential that the nursing should be good, and this would never be obtained so long as "handywomen" were tolerated. A maternity nursing service should be organised under direct medical supervision and control, and trained nursing should be placed at the disposal of a doctor whose patient was unable to make provision for it. Such a nursing service under the supervision of a sister midwife would ensure that accurate temperature charts were kept, and the onset of inflammatory processes would be recognised early. The nurse would report the presence of fever to the sister midwife who would at once inform the doctor. The present system of allowing the midwife full charge was fundamentally wrong, and would never be righted until there was properly organised medical supervision of this nursing. Dressings should be available for even the poorest patients, and such dressings would consist of an accouchement sheet, wool, binder, diapers, and towels. The dressings would be sterilised and the nurse would be responsible for those which should be returned. Antenatal centres should be established and should be available for all doctors engaged in industrial practices. The antenatal centre should be staffed by the general practitioner who resided in the area and not by whole-time officers or specialists.

The organised maternity service should work somewhat as follows. Each woman would select a doctor and would enter her name at the nursing centre. The doctor would carry out the antenatal examinations. Nursing service would be responsible for the routine urine examination and health visits. The doctor would be called to the confinement if required by the midwife, and certain routine visits would be paid during the puerperium. Consultant services should be available for any cases of difficult labour with which the practitioner could not deal. An emergency service should also be organised which would provide at short notice a nurse, blankets, hot water-bottles, transfusion apparatus, and, if necessary, a specialist. By this means, instead of transferring a shocked and collapsed patient to hospital the specialist and nurse would be rushed to the patient. The cost of this scheme could be met without making any demands on the State or the approved societies as the maternity benefit could be used for its administration.

ERRATUM.—Mr. N. Howard Mummery writes: "May I correct certain errors in the report of my paper recently read at the Royal Society of Medicine's Dermatological Meeting and reported in your issue of March 30th. I stated that the chief aim of an industrial medical officer was to prevent the occurrence of dermatoses. I did not state, as I am reported as saying, that, in the main, private or panel medical practitioners, or factory surgeons, had an inadequate knowledge of dermatoses. I said that they had an inadequate knowledge of the conditions of employment and of the home conditions of industrial workers. Further, I am made to say that I rejected for employment persons 'showing marks of seborrhœic states'; this phrase should read 'showing marked seborrhœic skin states.'"

BRITISH ORTHOPÆDIC ASSOCIATION.—The Robert Jones Medal and Association Prize for 1928 has been awarded to Mr. E. P. Brockman for his essay on Club Foot (Congenital Talipes Equinovarus).

BRITISH EMPIRE CANCER CAMPAIGN.—The quarterly meeting of the Grand Council of this Campaign was held on April 8th, with Lord Reading in the chair. The following grants to London institutions were made: £3500 to the Cancer Research Department of the Middlesex Hospital, £650 for research at St. Mark's Hospital, £80 for research by Dr. J. C. Mottram at the Radium Institute, and a sum of £500 for special investigations to be made at the Cancer Hospital under a scheme submitted by Dr. E. L. Kennaway.

The newly formed Cancer Research Centre in the North of Ireland was invited to become an affiliated body of the Campaign. The Council extended its congratulations to the recently organised New Zealand Branch of the Campaign, which was inaugurated during a visit to Wellington by Mr. Sampson Handley.

The summary of the recommendations made by the Committee of the International Conference on Cancer held in London last July, was submitted to the Council, which passed on the recommendations to the Investigation Committee of the Campaign. Inter alia the Committee strongly urges that the British Empire Cancer Campaign, in collaboration with the Medical Research Council and the Ministry of Health, should invite all institutions using radium and X rays to utilise an agreed form of record.

Reviews and Notices of Books.

COLOUR AND COLOUR THEORIES.

By CHRISTINE LADD-FRANKLIN. London: Kegan Paul, Trench, Trübner and Co., Ltd. 1929. Pp. 287. 12*s*. 6*d*.

THERE are three main theories of colour sensation. The first is the Young-Helmholtz theory, the basis of which is physical, founded on the proved fact that all the colours of nature can be imitated by three selected spectral colours in appropriate proportions. The second is that of Hering, the basis of which is chemical. It postulates a retinal mechanism which permits the alternate composition and decomposition of three different chemical substances by the action of light, giving rise to six different colour sensations, among which are included black and white. The third, that of Edridge-Green, is evolutionary, and shifts the mechanism for the distinguishing of colours from the retina to the brain, those individuals who are more highly developed in this respect being capable of distinguishing a greater number of colours than those who are less developed. Dr. Christine Ladd-Franklin, who is a psychologist, declares her main objection to the Young-Helmholtz theory to be that though the sensation white may be produced by a mixture of red, green, and blue lights, white is nevertheless not a red-green-blue sensation. We are asked to believe, she says, that when we experience the sensation of a faint colourless light we are really sensing red and green and blue without knowing it, and this idea, she says, is so bizarre that it would seem as if to mention it were enough to show its inadequacy. Dr. Ladd-Franklin's own theory, being a chemical one, approaches more nearly to that of Hering, but, she says, the fact that red and green must be regarded as a colour pair which, when combined, result in white, is fatal to Hering's theory; the combination actually produces yellow. Her own theory she terms the "molecular dissociation theory." The retinal basis of the light sense is a photochemical process, and the eye which furnishes the colour sense contains more complicated chemical substances than do the retinæ, which are defective. She supposes a chemical substance which under the influence of light undergoes dissociation, but whereas in the rods (which do not convey any colour sensation) this dissociation is at once complete, in the cones the process is more complicated and takes place in successive stages. In a primitive evolutionary condition, and also in the totally colour-blind individual, the cone process is absent—i.e., there is no partial dissociation and no colour sensation. In a more advanced condition the partial dissociation of the colour molecule gives rise to the colour sensations yellow and blue, a state of things which exists not only in the partially colour-blind, but also in the more peripheral parts of the retina where the cones are sparse, and also in twilight. A further dissociation of the molecules which give rise to the yellow sensation, or some of them, occurs in the normal individual, giving rise to two new sorts of molecules which excite the sensations red and green respectively.

The theory is both chemical and evolutionary, and in the latter respect has something in common with that of Edridge-Green, but whereas the latter regards the evolutionary process as cerebral, Dr. Ladd-Franklin looks for it in the chemistry of the retina. It is remarkable that although there is a detailed discussion in this book of the two older theories, that of Edridge-Green is entirely ignored. Certainly in one respect Dr. Ladd-Franklin's theory has the advantage, in that it is not inconsistent with monocular colour blindness, a condition which, though very rare, has occasionally been discovered. It is a pity that this book is not more systematically written. It consists in fact of reprints of a number of essays which have appeared in various periodicals from 1892 to 1927, so that there is a great deal of repetition without much logical sequence. At any rate, however, it provides material which cannot be ignored.

NEUROSURGERY.

Principles, Diagnosis and Treatment. By WILLIAM SHARPE, M.D., Professor of Neurosurgery, New York Polyclinic Hospital and Post-Graduate Medical School; and NORMAN SHARPE, M.D., Attending Neuro-surgeon, St. Mark's Hospital, New York. London: J. B. Lippincott Company. 1928. Pp. 762. £2 2*s*.

FEW comprehensive works on neurological surgery have appeared in recent years, though during that time the specialty has been one of the most active branches of surgery. The appearance of this rather expensive volume will therefore be hailed with interest; but the reader who hopes to find an accurate and orderly description of the more recent developments of neurological surgery will suffer disappointment. The book is an account of the authors' personal experience and consists for the most part of *ex cathedra* and oft-repeated statements of their somewhat heterodox views. Thus, undeterred by the experiences of the Great War, the authors advocate early laminectomy ("after the patient has rallied from the initial shock of the injury") for spinal injuries producing compression of the spinal cord. They also favour laminectomy in certain types of multiple sclerosis. For gliomas of the brain they prefer simple decompression to removal of the tumour and they are very pessimistic as to the outlook in these cases, though it has for some time been known that many gliomas possess a very low degree of malignancy and operation in these may be followed by freedom from symptoms for a number of years.

The first part of the book is devoted to surgical conditions of the brain. After a comparatively short chapter on tumours, brain abscess is discussed in an interesting way. The authors put forward a view which is unusual, but perhaps not unreasonable, when they urge that subtemporal decompression should be performed in most cases of temporo-sphenoidal abscess and that exploration of the brain for the abscess should take place through the subtemporal incision and not through the infected field of the mastoid operation. In the chapter on head injuries a short account is given of personal work on injuries at birth. The authors found from lumbar puncture in a series of some 500 newly born infants that intracranial hæmorrhage of varying degree occurred in 9 per cent. of the cases, particularly in first-born full-term males. They suggest that in these cases the early institution of repeated lumbar punctures will prevent the onset of cerebral spastic paralysis. Hydrocephalus, cranial deformities, the methods of neurological investigation and of cranial operations are discussed in turn. In subsequent sections, the surgery of the spinal cord, cranial nerves, and peripheral nerves is considered. There is also a chapter on the surgical treatment of early selected cases of purulent meningitis, in which the main point taken up by the authors is that in cases of localised purulent meningitis, associated with disease of the mastoid process, subtemporal decompression should be performed on the corresponding side of the head.

It will be readily gathered that the authors hold original ideas about neurological treatment and their book certainly stimulates the reader to reconsider the basis of many existing beliefs. They would have strengthened their work greatly if they had paid more attention to the orthodox views of the period and had introduced their points of controversy with detailed case reports and complete statistical information of their personal experience. Such cases as have been reported for the most part do not support the authors' arguments, or are so lacking in essential details that they arouse in the reader the suspicion that the book has been too hurriedly prepared.

X RAY EXAMINATION OF THE HEART.

Radiologia Clinica del Cuore e dei Grossi Vasi. By CESARE PEZZI, Professor of Medical Pathology, University of Milan. Milan: Cooperativa Farmaceuta. 1928. Pp. 331. Lire 40.

THE technique of X ray examination of the heart and great vessels has been greatly developed and perfected during recent years, and at the present time the X ray method must be considered as valuable as the electrocardiograph, if not more so, in the investigation of cardiovascular disease. Not only can the actual size of the heart be determined from the teleradiogram or orthodiagram, but valuable information is also obtained from a study of the contour of the heart and aorta viewed from different angles, and of the character of the pulsation.

Prof. Pezzi, in a monograph dedicated appropriately to Vaquez and Bordet, has given us a comprehensive account of the application of X rays to the study of the heart. He prefers orthodiagraphy to teleradiography as the most serviceable method of recording the exact size and shape of the organ, and he advocates the rather complicated system of measuring the orthodiagram elaborated by Vaquez and Bordet. After describing the technique employed, and the normal appearance and dimensions of the heart shadow, he discusses the modifications seen in disease, valvular lesions, heart failure, pericardial effusion and adhesions, hypertension, angina, and less common affections all being considered in detail. Three chapters are devoted to the aorta in health and disease, and here the illustrative radiograms are particularly good. On the subject of congenital malformations and of affections of the pulmonary artery Prof. Pezzi is a recognised authority, and the X ray appearances in these conditions are fully described. Expansile pulsation of the pulmonary arteries in the lung roots—the so-called hilum dance—is regarded as diagnostic of pulmonary incompetence. The text is profusely illustrated throughout by anatomical figures, orthodiagrams, and radiograms, and an adequate bibliography is given at the end of the book.

The treatise is likely to become a standard work on the increasingly important subject of the X ray examination of the heart.

THE SETTING OF FRACTURES UNDER THE FLUOROSCOPE.

La réduction des fractures sous écran radioscopique. By Dr. RADUTZESCO, formerly a Foreign Assistant in the Surgical Therapeutic Clinic of the Faculty of Paris of Dr. Pierre Duval; Surgeon to the Hospital "Regina Elisabeta" in Bucharest. Preface by M. PIERRE DUVAL. With 125 figures in the text and on 48 plates. Paris: Masson et Cie. 1928. Pp. 196. Fr.50.

Dr. Radutzesco in this small monograph describes and advocates a method of setting fractures, especially those of the lower end of the forearm and of the leg, with the help of the X rays and fluoroscopic screen. He sets forth the advantages of this method both in the reduction of the displaced bones in their fixation in plaster, and subsequently in examinations carried out to make sure that the correction and fixation remain satisfactory. He warns his readers against the dangers of frequent exposure to the rays and gives details of the precautions necessary to minimise the quantity of exposure. The special form of fluorescent screen used consists simply of an oblong screen, the "pelle radioscopique du Dr. Henri Béclère," measuring 13 × 18 cm., to which is attached a long handle set in a plane parallel to but above that of the fluorescent surface. Its obvious resemblance to a spade has suggested its name. The fluorescent material is covered by a piece of lead glass 10 mm. thick. Full details and a series of radiographs are given of seven cases of fracture near the wrist, one of the shaft of the humerus, and four of the ankle. Inhalation anæsthesia is recommended for the setting of fractures of the upper extremity and spinal anæsthesia for the lower. The results, immediate and remote, appear to have been excellent. Dr. Radutzesco points out that there are pitfalls awaiting the unwary in the application of this method, and he tells readers how to avoid them. The same methods might no doubt be used in fractures of other parts of the limbs, but less easily and less completely than in those of the wrist and ankle. They seem to us to be too elaborate to be practicable in the rush and hurry of a general hospital. In private work a surgeon with the necessary time, experience, and apparatus at his disposal may hope to secure excellent results with fracture treatment in this way.

GROWTH.

By W. J. ROBBINS, S. BRODY, A. G. HOGAN, C. M. JACKSON, and C. W. GREENE. New Haven: Yale University Press. 1928. Pp. 189. With 83 figures. 14s.

THESE five semi-popular lectures by members of the staff of the University of Missouri deal with the nature of growth, its statistical, nutritional, and morphological aspects, and the influence of the ductless glands. The most interesting perhaps is Prof. Brody's summary analysis of the course of growth and senescence, which deals with facts that ought to be familiar to anyone concerned with nutrition. Though when he gets away from facts, and says—e.g., "Why does growth occur? Because there is an inherent tendency which causes cells to divide," we could wish he had put a footnote "this is a joke" or "this is not a joke," as the case may be. The other four chapters are all good, and we can heartily recommend the book as an introduction to a great subject.

THE DIFFERENTIAL DIAGNOSIS OF BLOOD DISEASES.

Praktische Differentialdiagnostick. Teil 8. Blutkrankheiten. By Dr. ALBERT HERZ, Lecturer at Vienna University. Dresden: Theodor Steinkopff. Pp. 86. M.8.

THIS slender volume, containing less than a hundred pages, is a surprisingly complete synopsis of modern knowledge of blood diseases. It contains little that is new, but omits little that is important. The arrangement is logical, and reference is easy; but illustrations are scanty and poor, and technical details are inadequate and scattered through the text. It is, however, a satisfactory work for the purpose for which it was written, and many clinicians will probably find that this reasonably priced book will give an answer to the everyday problems of differential blood counts.

BACTERIOLOGY.

Morphologic Variation and the Rate of Growth of Bacteria. By A. T. HENRICI, Professor of Bacteriology in the University of Minnesota. London: Baillière, Tindall and Cox. 1928. Pp. 194. With 36 figures. 13s. 6d.

THE early ideas about the abundant pleomorphism of bacteria were completely upset by the discovery of adequate methods of making pure cultures. In the rebound there has been a long period in which bacteria have been thought to be much more uniform in size and shape than they really are. Prof. Henrici has been looking again at the forms of several species and measuring them at different stages of growth under various conditions, and he has made out that they change in accordance with plans which can be approximately ascertained. Some, at any rate, of the pleomorphism which has lately been supposed to represent life-cycles can be explained along these simpler lines; though the author does not deny the possibility of complicated modes of reproduction, he merely says they are not proven.

LE CANCER PRIMITIF DU POUMON.

Étude anatomo-clinique. By RENÉ HUGUENIN, Ancien Interne Lauréat des Hôpitaux de Paris; Préparateur du Laboratoire d'Anatomie Pathologique de la Faculté. Paris: Masson et Cie. 1928. Pp. 330. Fr.50.

THIS monograph appears at an opportune time. Lung tumours have been prominently under the notice of clinicians and pathologists during the last ten years, and although much has been written on the subject the information is scattered. A comprehensive and complete study such as Dr. Huguenin has made is therefore of particular value. The work has involved deep research into the literature as well as an intimate study of many cases which have come under the personal notice of the author. All aspects are treated exhaustively. Our ideas of the pathology of cancer of the lung at the present time are undergoing some revision, especially in regard to the nature and origin of the oat-cell tumours, and Dr. Huguenin shows a critical appreciation of the problems at issue. The question of ætiology, too, he approaches with caution. In the clinical section, and especially in that part concerned with diagnosis, some original observations have emerged from personal experience of the author and his colleagues. A large section of the book is concerned with descriptive notes of 46 cases of chest tumour. The histological drawings and skiagrams illustrating lung cancers are excellent. The monograph will doubtless take its place as a standard work on tumours of the lung and mediastinum.

WHITHER MANKIND.

A Panorama of Modern Civilisation. By 18 contributors. Edited by C. A. BEARD. London: Longmans, Green and Co., Ltd. 1928. Pp. 408. 12*s*. 6*d*.

THIS book is based on "the assumption that science and the machine are two invincible facts with which all must reckon. Those who refuse to face them are condemned in advance to sterility and defeat." It consists of 18 essays under the titles, Science, Business, Labour, Health, Religion, the Family, Play, and so forth, in which the respective authors speculate on where we are and where we shall be. It is, in short, yet another symposium on the spirits of the age and, as generally happens, the authors immensely overrate the importance of their catchwords and forget the spirit of the ages, of which any philosophical biologist could have told them; curiously enough there is no such collaborator in the list.

FROM THE SEEN TO THE UNSEEN.

By JOHN H. BEST, B.Sc. Lond., Vicar of Little Marlow, Bucks. London: Messrs. Longmans, Green and Co., Ltd. 1929. Pp. 552. 18*s*.

THIS is an attempt, well documented and supported by much scientific and philosophic knowledge, to prove that there is an existing God, Who, in the words of the Prayer Book, is the "Maker of heaven and earth, and of all things visible and invisible." Such being the proposition, its demonstration is proceeded with in an orderly manner. A preliminary section having discussed the chief characteristics of life, animal and vegetable, and the relations existing between plants and animals having been demonstrated, the doctrine of evolution is found not to militate against any of the arguments that can be adduced for belief in a Divine design. The following two sections deal with physiology and embryology on recognised lines, the summaries which close the sections being clear and instructive, and proving the author to have followed carefully the lessons of much reading and to have real skill in presenting those lessons briefly. Up to this point the author has been attempting to show, especially in the passages closing each section, that every attempt to arrive at the sufficient cause of embryonic development along purely mechanistic lines is doomed to failure. Now, in a section discussing memory and instinct, he emphasises the fact that the manner in which our memories are preserved strikes at the root of any theory which would explain the universe only in terms of chemical and physical forces. A section on astronomy and the possibilities of human life or life in any form on other planets brings us to a long concluding section in which the great ethical and religious situations now placed before the reader are discussed, together with the arguments for a belief in the hereafter.

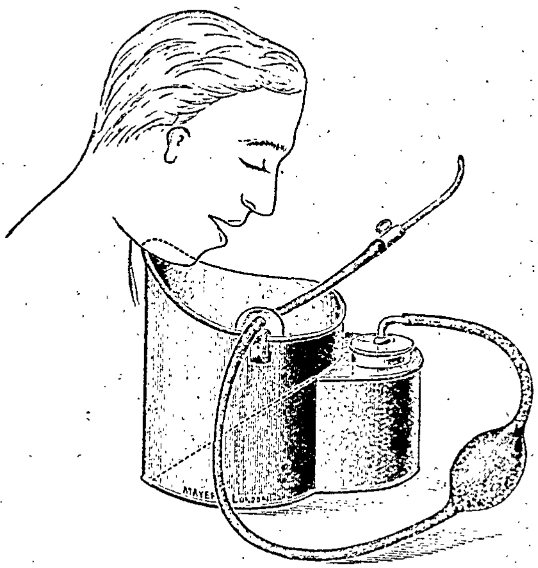
If there is no hereafter, the author pleads as the result of his arguments, not only will the evolutionary process to all intents and purposes have run its course in vain, but in vain will have been all men's efforts to bring their wills into harmony with God's through obedience to those higher impulsions which He Himself has put within them. The difficulties lying ahead of any writer who attempts to answer the fundamental questions involved in such an inquiry are familiar to everyone, and readers will judge for themselves whether the author's arguments establish what he so ardently hopes to be true. But his attempt to re-enforce faith in religion and to abate scepticism by reasoned argument is worthy of great praise for the labour expounded.

New Inventions.

A LAVAGE APPLIANCE.

MAINLY FOR THE ACCESSORY NASAL SINUSES.

UNLESS a gravity douche can is used the lavage of the accessory sinuses implies the holding by the patient, the nurse, and the surgeon between them two more or less clumsy vessels, the lotion holder and the receiver, both of which usually slop over, and a detached syringe. The apparatus illustrated is an attempt to overcome all these difficulties by combining the two chambers in one appliance. The can is held by the patient and the surgeon or nurse has both hands free to control the cannula and the syringe, which is securely held by its detachable fastener to the can. An assistant is not required and, if necessary, the patient, by placing the can on a table, is able to carry out the lavage unaided and in comparative comfort. The clip on the Higginson syringe is detachable.



The apparatus (which is shown disproportionately large) could be used equally well for eyes, ears, or any other part of the body, and in almost any position.

This model has been made for me by Messrs. Mayer and Phelps.

HUGH E. JONES, L.R.C.P. Lond., M.R.C.S. Eng.

THE LANCET.

ONDON: SATURDAY, APRIL 13, 1929.

N THE PASSING OF MUCH WATER.

YURIA is a symptom met with in many conditions,
ng from the heightened nervous tension asso-
l with (say) a medical examination for life
ance, when it appears in transient form, to the
nued passage of large quantities of urine in
is states such as diabetes insipidus and chronic
e of the kidney. In his Goulstonian lectures,
publication is complete in our present issue,
E. B. VERNEY has attempted to interpret the
logical polyuria of these two conditions in
of the findings and theories of experimental
ology. It has long been known that the polyuria
abetes insipidus can be controlled by the sub-
eous injection of an extract of the posterior lobe
e pituitary gland, and the natural conclusion has
drawn that the symptom is due essentially
me interference with the function of that body.
clinical observation has shown that destruction
isease of the whole hypophysis is not necessarily
wed by diabetes insipidus, while the results of
rimental extirpation of the gland have been
licting. The view, therefore, has been advanced
the polyuria is due to a disturbance of the
othalamus, leading to a failure of this part of the
n to regulate the output of water and chloride
the kidney, and is not directly due to a lack of
itary secretion. In a series of ingenious experi-
ts Prof. VERNEY demonstrates how the gradually
easing polyuria which develops when the isolated
ey is perfused in a heart-lung preparation can be
bited in a remarkable fashion, not only by adding
itary extract to the circulating fluid but also by
usion with the blood passing through the head
neck of another animal. He further shows that
n the pituitary body is removed from this animal
yuria is re-established. From these and other
eriments he concludes that the polyurias associated
h diabetes insipidus, with water ingestion, and
h isolation of the kidney, have an immediate
ology common to all—viz., a decline in the amount
antidiuretic hormone normally secreted by the
uitary gland into the circulating blood stream.
d he puts forward the interesting speculation
t in the development of vertebrate animals upwards
m the fish and amphibian, the demand for an
reased control over the salt-and-water metabolism
the body has been met by a corresponding change
the function of the pituitary gland.

n his second lecture Prof. VERNEY examines from
ew angle ROSE BRADFORD's fundamental observa-
ns on the effects of reducing by surgical means the
ount of kidney tissue in the dog. ROSE BRADFORD
l shown that after the removal of even a small
ount of the kidney it was exceptional for the urine
return to its original quantity and density, the
st usual result being a distinct increase in the
nary water. By perfusing in parallel two kidneys
the isolated state, Prof. VERNEY and his colleagues
nd that the functional removal of half of one
ney by tying a primary branch of the renal artery,
ulted in an immediate and similar polyuria from
t organ. It was found, further, that the chloride
cretion was increased relatively or even absolutely, but that there was a *profound fall in both* the percentage and absolute amounts of urea eliminated. The reduced kidney, in fact, responded at constant blood pressure exactly as though it were being subjected to an increase in perfusion pressure. What is the precise mechanism culminating in this response is not clear, but from the conditions of the experiment it obviously must be a strictly local one. On the basis of these experiments and the results of recent work on the physiology of the kidney, the lecturer seeks to explain the well-known series of events in chronic nephritis—the early disappearance of the rapid swings in the rate of urine eliminated by the healthy kidney during the daytime, the increase in volume passed during the night, the slight variation in the earlier stages from the normal in the water excretion, urea concentration, and chloride concentration tests with little or no rise in blood pressure, followed by increasing loss of kidney function, persistent rise of blood pressure and, finally, death from renal failure. He assumes that some toxin applied continuously or discontinuously to the glomerular vasculature leads to a gradual diminution in the efficiency of the renal units. Each must work longer to fulfil its function (of maintaining the constancy of composition of the "milieu interne") with the result that there is first a reduction in the normal periods of quiescence, and later increased activity night as well as day. The death of some of the units leads to the development of a greater pressure stimulus on the others with resulting secretion of a more copious urine which approaches the plasma in its composition. In time this intrinsically developed pressure is not sufficient, and a higher general blood pressure is demanded to increase the circulation through the kidney. This sustained rise in blood pressure is contributed to, Prof. VERNEY thinks, by a change in the activity of the vasomotor centre, resulting either reflexly from the kidney or from the presence in the circulation of abnormal substances.

The Goulstonian lectures are, in fact, full of highly interesting speculations, but the lecturer wisely asks, how are all these mechanisms correlated and integrated in the struggle to preserve the composition of the body fluids at their optimum? That question, as Prof. VERNEY remarks, is as yet unanswered.

PUBLIC CLEANSING IN GREATER LONDON.

SOME three years ago a deputation from the London County Council urged upon the Minister of Health the need for investigation of the means taken in London for the disposal of house or other refuse. The Council had received complaints of the nuisance caused to their new housing estate at Becontree by the large dumps of refuse at South Hornchurch, which had been accumulating for more than 50 years. These dumps, in some places 90 feet high, are used chiefly for the deposit of house and trade refuse from the cities of London and Westminster, the annual increment being in the neighbourhood of 350,000 tons, an amount probably in excess of that collected annually in Manchester. Although at the start these dumps were remote from a populated area, and more or less unnoticed, they now present a huge disfiguring mass, the peculiar smell from which is said to reach the southern part of the Becontree Housing Estate; they are frequently on fire, and the cloud of smoke may reach the houses now being erected within the urban district of Hornchurch. These and all the large uncovered riverside dumps are extensive fly-breeding grounds; the amount of rat infestation is also very great. They pollute the surface water in the large shallow pools as well as the open drainage channels in the marshland. Authorities of other areas outside London, chiefly in West Middlesex, where smaller editions of the Hornchurch dumps are found, have protested against their districts being made dumping grounds for refuse from other areas. Nuisance, however, is not inevitable with dumping. At Northolt, for example, where frequent complaints were made a few years ago, there has been little, if any, objection raised since direct labour has been employed and the principle has been adopted of dumping in shallow layers and covering the fresh refuse with suitable innocuous material. In Hertfordshire and Bedfordshire, where great quantities of London refuse are dumped, complaints have been forestalled and conditions greatly improved as the result of careful management on the lines of the tipping precautions laid down by the Ministry of Health.

In his recent report[1] to the Ministry, Mr. J. C. Dawes takes the view that the present system of barging to dumps is open to criticism, especially as there is little effective competition between the contractors concerned, who have no regard for sanitary principles. The mounds created in the course of brick-making are a case in point. Hundreds of millions of so-called stock bricks are made every year, especially in the vicinity of Sittingbourne, with the aid of London household refuse; "fine ashes" or dust must be added to the virgin earth, "cinder" or breeze being commonly the only fuel used in the clamps to burn the brick. The brick-making industry appears capable of utilising some 700 of the 3000 to 5000 tons of refuse produced daily in London. Many brickmakers consider that household refuse should be allowed to stand before use; the fine ash content is thereby increased, possibly by the breaking down of the organic matter in which it is lying or to which it is attached, and from which in the fresh state it cannot be separated. But during this period of maturing a nuisance is produced which, unfortunately, cannot be met by covering with soil. Mr. Dawes suggests the making of a technical investigation by the industry to determine the possibility of using only separated ashes and breeze, holding out the inducement that these two items may cost them less than the crude refuse.

The magnitude of the problem is clearly seen from Mr. Dawes's report. In the years 1925–26, the collection of 1,130,000 tons of London house refuse and 72,000 tons of trade refuse cost the huge sum of £660,460, or 11*s.* per ton; its disposal required another £448,809, at the rate of 7*s.* 6*d.* a ton; and, in addition, street cleansing cost £1,086,118. The main gist of the report is that expenditure could be reduced by the formation of a central cleansing body for Greater London, to undertake both collection and disposal. Such a procedure has its precedent in the Metropolitan Water Board, and in the arrangements, less complete it is true, for the common disposal of sewage from the metropolitan boroughs and some of the areas adjoining London. The pooling of water-supply or sewage disposal was simplified by the fact that most, if not all, of the component factors of these problems had long been known and, to some extent, worked out. In the collection of house refuse, although the requisites are known—for it is obvious that the refuse must be stored on premises in a sanitary manner, and the material collected by methods which avoid the scattering of dust—we have by no means reached any final solution, although those responsible for the work in London and its vicinity have been active in their search. Experimental work is being done on the methods of collection, the best receptacle used, and the mode of its storage on premises, the most suitable type of dust collecting vehicle; on the disposal side, improved methods of dealing with tips have been devised and employed, improvements have been made in the construction of dust incinerators and in the utilisation of the constituents of refuse, both before and after incineration. Seeing that London represents almost the largest conglomeration of dwellings and premises in the world, and the difficulties bear some proportion to the size of the area concerned, the measure of success already achieved is gratifying. But any committee appointed to consider the question of giving effect to the report will be confronted with difficulties owing to the absence of accurate data. No doubt by the extended exercise of existing powers a reduction could be made in the cost of collection, caused by overlapping of refuse collection and street cleansing services; on boundary roads between boroughs, for instance, refuse is collected and the roads are cleansed at the present time by different local authorities. Section 140 of the Metropolis Management Act, 1855, enables the London County Council to order that any street or line of street, which is in more than one borough, shall be placed under the exclusive management of one of the borough councils for such purposes as cleansing. The difficulties and expense of accurate costing will militate against the committee's obtaining reliable evidence as to the further possibility of reducing by any appreciable amount the cost of collection; in fact, it would seem probable that the adoption of methods of collection tending to increase its amenities will increase the cost. In the absence of suggestions for improvement of the best known methods of disposal at present available and already in force, it is difficult to see what can be done beyond recommending the extended adoption of these methods. In the near future it should be feasible to mitigate the nuisance caused by incineration plants, and it is not too much to hope that the attempts to use crude refuse as a fuel to produce steam for the generation of electricity will be better rewarded. When a measure of success has been obtained in both these directions it is possible that certain geographical combinations of London might bring about the extended use of inoffensive incinerators helping in the supply of electricity. A proposition more ready for application at the present time would be concerted action to reclaim by dumping the low-lying marshland on the banks of the Thames, incidentally a means of providing unskilled work for the unemployed.

◆

CANCER OF THE LUNG.

An important contribution to the study of cancer of the lung has lately been made by Dr. Georgiana Bonser,[1] who has compiled a statistical record of all the cases of intrathoracic tumour reported in the post-mortem room of the Leeds General Infirmary during the last 37 years. Her work is of special importance because her figures, unlike most of their kind, afford no evidence of an increase in the incidence of these tumours in recent years. The average percentage for the 37 years was 1·06, the highest figure, 1·30 per cent., occurring in the period 1908–12. This question of an increase in the incidence of intrathoracic tumours, a considerable proportion of which appear to be carcinomas of the bronchi, naturally interests cancer workers because it is surmised that air pollution may play a part in the ætiology of the condition. It has undoubtedly seemed to many pathologists, both in Europe and in America, that this form of growth is seen in the post-mortem room relatively more often than formerly, and in most places the figures, when analysed, have shown that this is indeed the case. Nevertheless it is fully appreciated that fluctuations in post-mortem room statistics may depend more on selection of suitable cases for demonstration purposes than on the actual incidence of the disease in the population. In Leeds this factor has not played a great part because, as Dr. Bonser points out, over 83 per cent. of all persons dying in the hospital during the last 37 years have been examined at autopsy. This is certainly an unusually high percentage for a hospital in this country and it makes her findings all the more significant. In 1927 J. B. Duguid[2] collected the cases from the post-mortem records of the last 60 years in the Manchester Royal Infirmary, and there it was found that the incidence was unusually high—on an average more than twice as high as that in Leeds—and that it was steadily on the increase. Since Manchester is especially notorious in respect of atmospheric pollution, comparison of the figures with those of other less industrial towns was expected to furnish some information about the relation of this form of new growth to the degree of contamination of the air. It is perhaps fortunate for the advancement of medical science that the first comparison was made by Dr. Bonser in Leeds, for the atmospheric conditions in that city are so far comparable with those of Manchester as to render the Leeds figures more suitable as a control to the Manchester ones than as a contrast to them. At all events the difference in the incidence of the tumours in the two towns was far greater than the difference in their atmospheric conditions, and factors other than air pollution must be considered as influencing the figures. Dr. Bonser further demonstrates how complicated is the problem by showing that although the incidence in the post-mortem room at Leeds has not increased, the percentage incidence in the wards of the hospital has shown a definite rise since 1914. She rightly suggests that improved methods of diagnosis and a greater clinical interest in pulmonary cancers of late years may be responsible for this, and it is evident that statistics gathered from the post-mortem records of general hospitals, while they give useful information on the nature of intrathoracic tumours, may yield very doubtful and conflicting evidence about the incidence of the disease either in the general population, or even in the wards of the hospital itself. Dr. Bonser's paper has strengthened the suspicion that the much discussed increase in lung cancers may be no more than apparent. In Leeds the occupational incidence reveals nothing of significance. The age and sex incidence is similar to that found in most other hospitals, the proportion of male cases to female being about 3½ : 1. But Dr. Bonser shows that in Leeds the proportion of male to female autopsies is roughly 3 : 2, and she is to be congratulated on being the first writer on this subject to publish, along with the incidence, figures showing what proportion of all deaths in the hospital go to post-mortem examination. It will be seen that this information greatly helps in assessing the true value of the figures, for it indicates that the disproportion between the sexes is not so great as at first appears.

---

[1] Public Cleansing, being a Report of an Investigation into the Public Cleansing Service in the Administrative County of London. By J. C. Dawes, O.B.E., M.I.Mech.E., Inspector of Public Cleansing, &c., Ministry of Health, H.M. Stationery Office, 15*s.*

[1] Jour. of Hygiene, 1929, xxviii., 340.

Dr. T. C. Hunt's paper, which appears on p. 759 of our present issue, treats the subject of cancer of the lung more from the clinical point of view, but attention is paid to the previous histories of pulmonary affections and their bearing on the ætiology. Of the 26 cases reported by Dr. Hunt from St. Mary's Hospital, half gave a history of previous disease of the lung. Influenza, which has been cited as an important ætiological factor, was reported in not more than a quarter of his cases. A similar proportion—about 30 per cent.—was revealed in a recent report by B. R. Kirklin, R. Paterson, and P. P. Vinson on 68 cases of pulmonary tumour from the Mayo Clinic, and these authors justly remark that this incidence is not unduly high in view of the recent pandemics. Indeed, with the prevalence of the condition or conditions which the laity loosely term "influenza," it is surprising that so few of the patients claimed to have suffered from it. Tuberculosis, from these reports, does not appear to be a very common associate of lung cancer. Bonser found record of old or active tuberculosis in 26 of her 172 cases, Hunt finds it in only 2 in his 26, and Kirklin in none of the 68 cases from the Mayo Clinic, so that respiratory infections do not seem to play a very important part in the ætiology. Dr. Hunt draws special attention to the frequency with which pain marks the onset of symptoms in cancer, in contrast to phthisis in which pain is a comparatively uncommon early symptom. This is undoubtedly one of the most valuable points in differential diagnosis, and attention to it may make the early recognition of pulmonary cancer more certain. Perhaps many of the difficulties in diagnosis will be dispersed when it becomes more widely recognised that these tumours are fairly common, and are always to be borne in mind when investigating a chest case. The idea that lung cancers are little known rarities, only to be encountered once or twice in a lifetime, unfortunately dies hard.

Annotations.

"Ne quid nimis."

THE BRITISH CONGRESS OF OBSTETRICS AND GYNÆCOLOGY.

Dr. Gibbon FitzGibbon will preside over the seventh British Congress of Obstetrics and Gynæcology which meets at Dublin on the 24th of this month. The proceedings open with a discussion on the Management of Cases of Pelvic Disproportion, at which the speakers will be Prof. Munro Kerr, Prof. Fletcher Shaw, Dr. James Young, Dr. J. D. Barris, Dr. Bethel Solomons, and Dr. W. Taylor. This discussion will occupy both morning and afternoon, and in the evening the President and Mrs. FitzGibbon will entertain members of the Congress and their friends at the Royal College of Surgeons, St. Stephen's Green. Communications on the two following days are to include papers on metropathia hæmorrhagica (Dr. Wilfred Shaw), the complications of ovarian tumours (Prof. James Hendry), the use of glycerine in obstetrics and gynæcology (Dr. Caroline Elliott), double monsters (Dr. A. L. Mudaliar), eclampsia and its renal lesions (Mr. R. H. Paramore), mercurochrome in urinary infections in pregnancy (Prof. D. C. Rayner), the basic cause of cervical cancer (Dr. K. V. Bailey), fœtal death following quinine induction (Mr. A. A. Gemmell), the technique of radium application in uterine carcinoma (Mr. Gilbert Strachan), and pregnancy following X ray stimulation of the ovaries (Prof. Miles Phillips). The official guests of the Congress are Prof. John Osborn Polak, of New York, who will contribute a paper on Follow-up Results in 500 Cases of Uterine Hæmorrhage of Non-malignant Origin, and Prof. Ludwig Adler, of Vienna. An exhibition of pathological specimens has been arranged in the Royal College of Physicians, and will be open for inspection after midday on Wednesday. Those who have specimens to show are requested to communicate with Dr. J. Lait, School of Pathology, Trinity College, Dublin, without delay; drawings or photographs of interesting cases or specimens being also welcome. The Congress dinner will be held at the Royal College of Surgeons at 7.45 P.M. on Thursday, the 25th, and the sessions will end at 1 P.M. on Friday, the afternoon being reserved for operative demonstrations. The hon. secretaries of the Congress are Dr. Bethel Solomons, Master of the Rotunda Hospital, and Dr. Gerald Tierney, 22, Lower Baggot-street, Dublin. The meetings will take place in the hall of the Royal College of Physicians in Kildare-street.

THE FLEA AT SEA.

ONE of the most important measures for preventing the spread of bubonic plague is the elimination of flea-bearing rats from ships. For some years now the English and Australian health authorities have been searching incoming ships for signs of rat infestation as a preliminary and guide to anti-plague measures. In 1925 C. V. Akin and G. C. Sherrard showed that rat infestation could be estimated very accurately, but when a ship is heavily infested no amount of fumigation seems to clear it. Several observers have shown that rats can be trapped on ships after fumigation, and this fact must be due to the presence of retreats in the ship's structure where rats can go but fumes cannot reach. For this reason rat-proofing of vessels has been advocated, for even if it does not in fact make the ship rat-proof it makes it much more vulnerable to fumigation. That it takes a long time to establish a rat-colony on a properly cleared ship has been shown in a recent paper by C. L. Williams, of the United States Public Health Service.[1] He investigated 1913 "ships" in New York harbour during two years, each fumigation counting as a "ship" in this enumeration. The rats were almost exclusively the black rat and his close relative the Alexandrine rat. As would be expected, twice as many rats were found on ships carrying a cargo suitable for rat food than on the others, and the nature of the cargo seemed to be the major rat-influencing factor. An outstanding result of the investigation was that the majority of rats are carried by relatively few ships and that most ships carry few rats. Only about 10 per cent. of the ships arriving at New York were heavily infested (more than 30 rats), and these are the vessels that constitute a menace to the public health. The really large rat colonies were found in ships fumigated at intervals greater than four months. Apparently the majority of ships return to their normal rat population about five months after fumigation, and ships found free of rats at one fumigation are usually free at the next one, whether this be two, three, or six months later. The obvious conclusion is that most ship rats are born on the ships they infest and that fumigation of every ship is a waste of money. Better results would be obtained by concentration on the few ships known to be infested. It is clear, however, that if this were to become the practice quarantine officers would have to keep a very careful look-out for new infestations, which do, of course, occur from time to time. For instance, a South American coaster yielded only seven rats on the first 13 fumigations while the fourteenth produced 143; the officers testified that the rats all came aboard in a single cargo of potatoes.

Another important observation made by Mr. Williams is that only two varieties of flea were found on ship rats in sufficient numbers to be of practical importance. These were *Xenopsylla cheopis* and *Ceratophyllus fasciatus*; other varieties were apparently only accidental passengers. His results agree with those of J. C. Gauthier and A. Raybaud at Marseilles, of W. Fromme at Hamburg, and of Newstead and Evans in Liverpool in finding *X. cheopis* by far the commonest flea. C. Tirboschi, at Genoa, S. Kitasato in Yokohama, and Schastry in Odessa found no other flea at all in their surveys of ship rats. The flea catch in New York varied quite definitely with the temperature, but humidity made little difference. Below 50° or 55° F. the numbers were very low, but the slower reaction rate of a fumigant in cold weather must be taken into account before assuming that there are far fewer fleas on rats in the winter. Probably both factors operate. Most of the fleas came from the Caribbean and the east coast of South America; ships plying only between northern ports harboured mainly *C. fasciatus* and did not seem to be a grave plague menace. The southern ships mostly carried rat-food cargoes, touched at many ports, and entered dock in most places. Sugar ships as a class had few rats and no fleas. The fumigant used had considerable influence on the number of fleas found; when Zyklon B was employed less than half as many fleas per rat were found as when generated gas or sprayed liquid were used.

As a result of his investigation Mr. Williams recommends that removal or closure of rat harbourages in ships should be required; that complete rat eradication should be substituted for the specified two hours' exposure to fumigation, and that ships should be fumigated on the basis of observed rat infestation, after giving due consideration to the potentialities for plague infection in each case. He adds that it is essential that inspections should be made only by highly efficient, conscientious, skilful employees who have undergone a lengthy period of special training.

OLEOTHORAX.

INTRAPLEURAL injections of antiseptic oil were advocated by Bernou in 1922 in the treatment of purulent tuberculous effusions and pleuro-pulmonary perforations. For this purpose a volatile antiseptic dissolved in olive oil or paraffin was injected in an amount sufficient to fill the affected pleural cavity. The particular antiseptic used by Bernou was the somewhat mysterious French proprietary remedy known as gomenol, believed to be a distillate from the leaves of niavul (*Melaleuca viridiflora*). The success attained by the method soon led to its wider application, particularly in the treatment of progressive pleural adhesions in cases of artificial pneumothorax. A. Courcoux and A. Bidermann,[1] in a recent contribution, point out that the beneficial effects of oleothorax depend on its mechanical action in maintaining a positive pleural pressure and in separating pleural surfaces which would otherwise adhere and on its antiseptic action in chronic purulent tuberculous pleurisies. The success of artificial pneumothorax treatment is often threatened by the formation of pleural adhesions which cause a progressive reduction of the pleural cavity and a corresponding re-expansion of the underlying lung. In such cases the usual practice is to raise the pleural pressure and shorten the intervals at which refills are given, but the resulting benefit is, as a rule, only temporary. The substitution of oil for air prevents contact between pleural surfaces and enables a more constant pressure to be maintained. If success is to be obtained the pleura must be completely filled with the oil and rigorous control by X ray observations is essential. Undue mobility of the mediastinum which yields before a positive pressure and prevents adequate collapse of the diseased lung is another occasional cause of failure in artificial pneumothorax treatment. The authors suggest that in such cases small injections of oil may provoke local reactions, the formation of mediastinal adhesions, and consequent fixation. They hold that there is no evidence that the oil has a solvent action on adhesions, but that the pleura tends to thicken under its action. This effect may indeed lead to disastrous results, for in the presence of dense adhesions a weak-walled pulmonary cavity may rupture if the pleural pressures are raised too high. In purulent tuberculous pleurisies oleothorax is the method of choice if air replacement has failed to prevent reaccumulation or if secondary infection has occurred. Other indications for the induction of oleothorax are small pleuro-pulmonary perforations, too rapid absorption of air in an otherwise successful artificial pneumothorax, and when for any reason frequent refills are undesirable. In this country F. G. Chandler[2] has suggested oleothorax in the treatment of bronchiectasis, a condition in which artificial pneumothorax treatment seldom causes a satisfactory collapse of the diseased lung. Before commencing oleothorax treatment a preliminary injection of oil should always be given. If the pleural membrane is unduly sensitive a sharp reaction may occur manifested by pyrexia and effusion. In such cases caution will be necessary. Pleural shock may endanger life in this as in other forms of treatment involving pleural puncture. Too hasty raising of pressures may result in pulmonary rupture, while if a broncho-pleural fistula is patent the injection of oil may cause acute distress. A wise selection of cases and a careful technique are essential if success is to be attained.

PROGNOSIS IN HAY FEVER.

INOCULATION against hay fever should preferably begin by March, but many a sufferer from this complaint had forgotten what is in store for him until reminded by the spell of fine weather which we have been having. The practitioner faced with a request for prophylaxis will find guidance in an article,[3] contributed by Dr. John Freeman to our series on Modern Technique in Treatment, but, needless to say, a certain number of people are unwilling to take a course of injections unless convinced that they will gain a more than passing benefit. This question of ultimate prognosis has lately been dealt with by Dr. F. M. Rackemann,[4] of Harvard University, and it may be of interest to summarise his conclusions. "Every patient," he says, "wants to know what are the chances that the treatment of *his* hay fever in any one year will lead to results which will be permanent, and if not permanent, whether the immediate procedures will modify other treatment in later years." The answer to these questions is attempted by a scrutiny of the results of treatment, mainly by pollen injections, of 410 persons suffering from hay fever caused by ragweed. Only those who began their treatment in or before the season of 1925 and who were followed up for at least two years, are included in the tables. The number freed from the attacks for two successive years or more is disappointingly small—namely, 26, or 6·3 per cent. A review of the causes of this smallness shows several important features. Rackemann believes that a cure cannot be assured by persistent annual repetition of treatment; indeed, patients who need such annual repetition are unlikely to be cured by the methods at present available. In the small cured group the extent of the cure amounts to freedom for an average period of four years only. Thus far, and no further, do the present data warrant any conclusion. Statistics give the impression that the therapeutic extracts vary slightly in different years, and Rackemann goes so far as to say that "relief of hay fever is not always and necessarily dependent upon the particular treatment." These results, as he says, are distinctly disappointing, but more encouragement can be derived from his other deductions that an "improved" patient has a good chance of ultimately joining the "cured" group, and that in patients requiring annual courses, fewer and fewer inoculations will be necessary. The paper concludes with observations that dermal and general constitutional sensitiveness often persists long after clinical improvement is reached. Cure of hay fever by inoculation is clinical rather than truly immunological, and it is suggested that the conjunctival and nasal mucous membranes may become locally less sensitive.

THE POTATO AS CULTURE MEDIUM.

FOR the most distinguished research in the field of tuberculosis during the year 1928 the award of the American Association for the Advancement of Science has gone to Dr. H. J. Corper and Dr. Nao Uyei, of Denver. For some time these workers have been looking for a culture medium for the tubercle bacillus which would rival guinea-pig inoculation test in making a diagnosis. Of existing media Calmette's potato-cylinder was found to be the most efficient for growth of the bacillus in high dilution; but this medium had the disadvantage that it was also a suitable pabulum for contaminating organisms. In order to get rid of the latter the Denver doctors treat the supposedly tuberculous material with an equal volume of either 6 per cent. sulphuric acid or 3 per cent. hydrochloric acid and mix thoroughly in a centrifuge. Further, the growth-promoting properties of the *potato-cylinder were enhanced by the addition of small* quantities of a dye—viz., crystal violet—the most favourable dilution of this was found to be 1 part in 75,000. Their latest observations[1] show that they have been engaged in further simplification of their method and in comparing its value in practical tests on sputum, urine, and animal tissues with Petroff's method and with guinea-pig inoculation. They attempted to substitute a medium with ground potato for the crystal violet potato-cylinder broth medium previously described. At first they were unsuccessful, for the grinding in some way spoiled the potato. But it was found that if the potatoes are autoclaved for 30 minutes at 15 lb. pressure before being ground a successful glycerol-crystal-violet-potato-agar medium may be prepared. Exact proportions are still the subject of investigation, but it already appears that the glycerol content must be about 2–2½ per cent. and that the concentration of the dye should be only about *one-fifth* of that used in the potato-cylinder medium. In actual successes, or positive findings, the new method has proved equal to guinea-pig inoculation and definitely superior to the sodium-hydroxide-gentian-violet-egg medium. Among the practical advantages over guinea-pig inoculation may be mentioned economy, possibility of repeated observations, and the availability of a culture when positive.

THE XANTHOPROTEIC REACTION IN RENAL DISEASE.

THE grave clinical phenomena of true uræmia cannot with certainty be attributed to any of the substances investigated in this connexion such as urea, the amino-acids, uric acid, or creatin. It is only a few years since Becher and others have taken into particular consideration in investigating uræmic poisoning a group of substances of the aromatic series, such as indican, which are derived from intestinal putrefaction. Such substances, which are highly toxic, by their passage through the liver undergo a process of oxidation which renders them less toxic and rapidly eliminated by the urine. In normal conditions they are found in the blood in very small quantities, while in renal insufficiency they accumulate in large amounts. Becher with a special technique has instituted a xanthoproteic reaction to estimate the amount of soluble aromatic substances present in the blood. F. Tonietti, of the Institute of Clinical Medicine at Rome[2] has made a series of observations on 68 cases estimating the xanthoproteic reaction by Becher's method, using Ambard's formula for the urea index, and Jolles's test for indican in the blood by way of comparison. He found in numerous patients with acute glomerular nephritis the reaction was within normal limits, the same being true of the indican and nitrogen content. In a case of uræmia with convulsions occurring during the course of acute nephritis with a high nitrogen retention the xanthoproteic reaction was negative. This is an interesting fact to which Becher has also called attention—namely, that in the course of acute nephritis even when convulsive seizures manifest themselves the permeability of the kidney to the aromatic group remains good. Negative results were obtained in patients with renal tuberculosis, syphilitic nephrosis, and in nephrosis of pregnancy. In cases of diffuse chronic nephritis in various stages in which symptoms of uræmic intoxication were absent, the Xanthoproteic reaction showed a tendency to rise above normal, but in instances of grave symptoms of true renal insufficiency with more or less marked signs of uræmia the reaction reached a high degree indicating the retention of aromatic substances in the blood. The highest values were found in cases of uræmic coma and in primary or secondary renal sclerosis with uræmic intoxication. It is worthy of note that consecutive examinations showed an accentuation of the xanthoproteic reaction parallel with an aggravation in the symptoms and, on the other hand, it descended to normal limits with the disappearance of these symptoms. In these cases there is an evident agreement between the retention of aromatic substances in the blood and the occurrence of that form of uræmic that goes under the name of true uræmia in contradistinction to the slow and progressive course of grave toxic nervous symptoms of depressive type. On the other hand, in uræmia with convulsions the permeability of the kidneys to aromatic substances remains good and if this phenomenon is, according to Becher, a proof of a real difference between these two forms of uræmia, it is easy to understand how the evidence of an accumulation of such aromatic substances in the blood may have an important diagnostic value inasmuch as it allows these two forms of uræmia to be differentiated by a chemical reaction of very simple technique. There seems to be a certain degree of agreement between indicanæmia and the xanthoproteic reaction. In none of the patients with acute nephritis was the titre above normal, and all those with true renal sclerosis with more or less severe symptoms of uræmic poisoning showed a high titre, but while in some cases of uræmic convulsions the indicanæmia reached a high figure, in others with an equally grave symptomatology the amount was much lower. Hence the xanthoproteic reaction seems to be in greater agreement with the clinical symptoms of uræmia than does the amount of indican in the blood. From these observations of Dr. Tonietti it would seem that the xanthoproteic reaction is normal in cases of renal disease without renal insufficiency, and that in renal sclerosis it shows retention of aromatic substances in the blood when symptoms of absolute renal insufficiency make their appearance. Moreover, in true uræmia and anuria of whatever nature, the xanthoproteic reaction reaches high figures and this increase or persistence is of unfavourable import. Finally, although this reaction by no means always runs parallel with the level of indican and urea in the blood, it is in more constant agreement with the symptoms of renal insufficiency than the other two.

OCCUPATIONAL ANÆMIAS.

MUCH of our knowledge of the anæmias has come from occupational toxicology—from such apparently diverse sources as research on chronic benzene poisoning, toxæmias from amido- and nitro-derivatives of benzene, and the distribution of lead in the tissues in cases of plumbism. Facts associated with a fresh hazard now seem to link up the whole. This hazard is associated with the absorption of mesothorium into the body while applying luminous paints to watch-dials. Girls doing this work adopted the habit of pointing their paint brushes between their lips and so could in a week swallow from 7 to 200 microgrammes of radio-active substances, since the paint contained mesothorium and zinc sulphide. Not less than 15 girls who were thus employed in New Jersey broke down in health and died, often exhibiting symptoms similar to phosphorus necrosis, and a good deal of publicity in the United States has been given to these cases, much research being devoted to their elucidation. Dr. H. S. Martland, who has now summarised the whole story in two useful papers,[1] says that mesothorium when swallowed is absorbed and finally deposited, like lead, as an insoluble sulphate in the bones. Here it decays and disintegrates, giving off injurious alpha rays in the process. Should there be any septic infection, as, for instance, in the mouth, bone necrosis follows; but otherwise these injurious rays bombard and damage the neighbouring hæmopoietic bone-marrow. Hence may result leucopenic anæmia of the regenerative type with the presence of basophilic red cells, the condition, although more acute, recalling the anæmia of lead poisoning. Should this stage be survived, a more chronic type of disease may develop with low-grade crippling osteitis and aplastic anæmia. The condition of the blood now resembles that seen in chronic benzene poisoning, and apparently the marrow is so damaged as no longer to function. Contact with radio-active substances and X rays is a recognised cause of anæmia, either regenerative or aplastic in type. In the case of the New Jersey painters the existence of mesothorium was demonstrated during life by detecting emanations in their expired breath and after death by examining the tissues, when the bones in particular and the spleen were found to be depositories of this substance. No treatment can be of avail once the insoluble sulphate of mesotherium is laid down in the bones, and only time can help. Mesothorium decays half away in 6·7 years; in 12 years, therefore, a survivor should be safe. No case of poisoning has come to light in the watch industry in Europe or elsewhere, but only in America was the habit adopted of pointing the brushes with the lips. Knowledge of causation is naturally followed by abolition of risk, and so this occupational disease must disappear. But it will continue to live for the light it has shed upon the occurrence of anæmias.

THE METABOLISM OF THE ESKIMO.

THOSE conscientiously engaged in the elucidation of physiological problems by means of animal experiments must have constantly before their minds the knowledge that the results obtained with one species of animal may not necessarily apply to another species. Even different races or breeds of the same species of animal may show striking differences in their physiological behaviour. For instance, it has been shown that alone, among the breeds of dog, the Dalmatian has the capacity of excreting large amounts of uric acid in the urine. It should not, therefore, be altogether surprising if among the races of mankind we meet with fundamental differences in normal metabolic processes. The Eskimos are peculiar among human races in that their usual food consists almost entirely of protein and fat. Virtually the only source of carbohydrate in their diet is the glycogen present in the meat they consume, for the geographical conditions under which they live are such that, at least during the greater part of the year, it is impossible for them to obtain carbohydrate from any plant source. According to Heinbecker,[2] who has recently published a report on certain aspects of the metabolism of the Eskimos, from one-third to one-half of the total quantity of food eaten by them in cold weather is in the form of fat; in the warmer weather fat might furnish only one-seventh of the total quantity. Even when the maximal amount of fat is eaten, however, the Eskimos showed no signs of ketosis. The protein which makes up the rest of their dietary furnishes potential supplies of carbohydrate, and it has been suggested that such carbohydrate may be formed in sufficiently large amounts to counteract the ketogenic effect of the fat consumed. However, Heinbecker made some observations on the effect of starvation on the excretion of ketone bodies by Eskimos and found that they showed a very much milder degree of ketosis than is observed with fasting men belonging to other races. He suggests that there may be two fundamentally different mechanisms for dealing with fat in the human body, only one of which may require the simultaneous katabolism of carbohydrate. The Eskimos appear to need less carbohydrate to burn up fat than other races, and this may mean that their consistently low carbohydrate diet is associated with an increase in the effectiveness of that secondary mechanism which is independent of carbohydrate. He does not discuss the question whether this second mechanism is inherited in a peculiarly effective degree as a racial characteristic, or whether it is a result of individual adaptation to the prevailing dietetic conditions. The Eskimos were found to have an extremely good tolerance for carbohydrates. In fact, their blood showed rather less than the normal rise in sugar content after the ingestion of large quantities of sugar, and sugar never appeared in the urine under these conditions unless the subjects had previously been starved. There was, therefore, no hereditary or acquired alteration in their capacity for dealing with carbohydrates. One other point of interest emerged from Heinbecker's observations—namely, that the long-continued consumption of what would ordinarily be considered excessive quantities of protein had no demonstrable ill-effects on the Eskimos. They could deal perfectly well with the large quantities of nitrogenous material supplied to them and in no single case were signs of renal insufficiency met with. There is no need to assume that we are dealing here with any racial characteristic, for arctic explorers of European extraction have reported that after many years of living under similar dietetic conditions there have been no signs of any impairment in the efficiency of their renal or vascular systems.

RESEARCH ON ANÆSTHESIA: THE HICKMAN MEMORIAL.

THE appeal published in our correspondence columns, over the signature of Mr. Cecil Hughes, for initiating further research on anæsthesia is one that will commend itself at once to the medical profession in this country. It is noticeable that while the first great steps in anæsthesia, after its introduction in America, were British, yet of recent years new drugs, new methods, and new knowledge in connexion with anæsthetics are rarely our native product. The history of anæsthesia is one on which every Englishman, as well as every Scotsman, can look back with pride. The names of Hickman, Simpson, and Snow are inscribed for all time on the list of pioneers in this beneficent branch of practical medicine. Naturally we cannot expect a constant stream of great or original investigators in this work more than in any other department of scientific work. It looks, however, as though for some reason or another research work at all is altogether lacking or extremely scanty in Great Britain. Intratracheal administration of anæsthetics comes from America and spinal anæsthesia from the Continent, and although it is true that probably in the use of these methods and certainly in the use of general anæsthesia our practice is on a higher general level than that of Continental countries or even of the United States, yet it is to them rather than to ourselves that belongs the credit of initiating the methods which we pursue. The reason for this anomaly is not obvious. It may be that the practical Briton has been more concerned to perfect the human applications of anæsthesia as it is presented to him than to seek alternative and superior modes in the laboratory, or it may be that this particular and very difficult line of inquiry has not appealed to research workers because of certain inherent fallacies in the application of experimental results in anæsthesia to the human subject. Whatever the reason it is a pity that experimental research in anæsthesia should fall behind clinical excellence in this country. In some respects anæsthesia even at its best is still crude. Who, for example, can guarantee freedom from after-sickness in a formidable proportion of cases? Who, indeed, can tell the true pathology of this condition or supply anything but empirical remedies? Certainly improved technique has made this trouble less formidable than it used to be, but it is still one to be reckoned with, and supplies—even if there were no others—a first-rate problem for solution by research work in anæsthetics. We trust that the response to the appeal may prove sufficient to found a Hickman medal for original work.

THE OPHTHALMOLOGICAL SOCIETY'S CONGRESS.

DURING the last three days of this week the annual Congress of the Ophthalmological Society of the United Kingdom is being held in London, and there is every indication of a successful gathering. The subjects of the two principal discussions, on Thursday and Friday respectively, are Heterophoria and the Diagnosis and Treatment of Ocular Tuberculosis, the openers of the first being Mr. E. E. Maddox, Mr. Charles Goulden, and Group-Captain E. C. Clements, and of the second Sir Arnold Lawson, Dr. R. A. Young, and Mr. S. H. Browning. The morning of each day is being devoted to communications by individual members of the Congress, whilst for Friday afternoon, from 2.30 to 5, a clinical meeting has been arranged at the new Royal Westminster Ophthalmic Hospital in Broad-street, Holborn. By courtesy of Sir Joseph Petavel, F.R.S., the director, a visit is to be paid on Saturday afternoon to the National Physical Laboratory at Teddington.

Dr. T. Izod Bennett has been appointed Dean of the Middlesex Hospital Medical School in succession to Mr. Eric Pearce Gould.

Mrs. Margaret McGregor, of Stirling, has left £20,000 to the University of Glasgow to establish a chair in connexion with medical research.

PRINCESS MARY AT BRADFORD.—On Thursday in last week Princess Mary opened two infants' wards, a sunlight department, and a nurses' home at the Bradford Children's Hospital.

ANCOATS HOSPITAL, MANCHESTER.—The report of the medical board of this institution for 1928–29, submitted by the chairman, Mr. Arnold Renshaw, contains a summary of the extension of the methods of investigation to which many special types of disease are to-day submitted, and Mr. Renshaw indicated that during the next decade the special departments of Ancoats will require increased equipment to keep pace with modern knowledge and technique, laboratory work in particular having considerably increased in extent and application. In view of the extension of the municipal health services, and of the municipalities taking over the present poor-law hospitals, a greater onus, he points out, will be placed upon the voluntary hospitals to devote themselves to more specialised and serious disease, if by the force of an individual enthusiasm and zest for advancement and research they are to lead the van of medical progress. "The problem of the future," runs the report, "is how to apply these highly developed, precise scientific methods of individual diagnosis and treatment to patients in the mass without losing the thread of continuity of observation in any one patient." The solution of the problem is found to lie in finance, ample equipment and space, careful organisation, expert supervision, and enthusiasm.

The Clinical Interpretation of Aids to Diagnosis.

A Series of Special Articles contributed by Invitation.

XXVII.

THE SIGNIFICANCE OF ORGANISMS IN THE URINE.

I.—PRELIMINARY TESTS FOR INFECTION.*

THE presence of organisms in the urine is direct evidence of an infection of some part of the urinary tract, provided that the specimen has been taken with due precautions against contamination from external sources including the urethral meatus and the surrounding parts. A cellular reaction almost invariably accompanies bacterial infection. No bacteriological examination of urine is therefore complete unless the cellular content is also investigated. Where possible, both cellular and bacterial content should be estimated quantitatively, otherwise no proper judgment can be given as to the significance of small numbers of cells or organisms. Furthermore, the analysis of the various types of cells present, and a search for casts and crystals, often furnish valuable help in locating the exact site of an infection.

Organisms and Cells in Small Numbers.

The presence in small numbers either of organisms or of cells does not necessarily indicate a pathological state. Quite commonly, a few meatal organisms, usually *Staphylococcus albus* or diphtheroid bacilli, find their way into a specimen during the passage of a catheter and yield a growth on culture; again, first morning catheter specimens from apparently normal individuals frequently contain a few leucocytes. The clinical history together with experience in the quantitative evaluation of such findings will usually decide whether they signify infection or pyuria.

Apart from meatal contamination, a point frequently raised is whether the finding of one or two definitely pathogenic bacteria in a catheter specimen of urine may not be due to a power possessed by the kidney of removing organisms from the blood stream —a question most often asked in regard to tubercle bacilli. It is now generally believed that a healthy kidney will not pass micro-organisms; that the presence of tubercle bacilli in the urine (excluding tuberculosis of the urinary tract below the kidney) implies a tuberculous lesion of the kidney; that in typhoid fever, septicæmia, or scarlet fever, whenever the causative organism is found in the urine, there must be a renal lesion which allows the organism to pass the kidney even though the lesion may be too small to produce renal symptoms.

Infection in the urinary tract may involve the kidney substance, the renal pelvis, the ureter, the bladder, or the urethra and its ducts. A positive bacteriological examination should assist in pinning down the infection to one or more of these sites if the organisms having a predilection for the various sites are known and if the bacteriological and clinical findings are correlated. From the practitioner the bacteriologist will require a properly collected specimen and a reasonable history of the case. The history, so often withheld, is of great importance in that it enables the bacteriologist to select the most suitable medium for obtaining successful cultures.

Collection of the Specimen.

A catheter specimen affords the only reliable positive information as to bacterial content, except when the urine is to serve simply as an index of urethral infection. Admittedly, it is not always desirable to use a catheter in practice, and it is a reasonable argument that if an ordinary specimen contains no organisms then a catheter specimen certainly will not. The preliminary examination of a "cleaned up mid-stream" specimen is therefore a useful procedure and, if negative, is entirely reliable; but if such a specimen contains organisms, catheterisation must be performed unless the bacteria can, with certainty, be classed as contaminants.

Catheter specimens should be received into a sterile flask or glass-stoppered bottle and should be examined as soon as possible after collection. If there is undue delay delicate organisms such as streptococci tend to die out, pus is liable to disintegrate and disappear, whilst, in hot weather, coliform organisms may so multiply that the number present gives a false idea of the severity of the infection. In all cases the first morning specimen supplies most information, and it is the only specimen of any value for quantitative and comparative work.

Males.—Non-catheter specimens from the male must of necessity contain the washings from the urethra; even a mid-stream specimen will contain prostatic or urethral pus and bacteria if infection in these sites is heavy. "Cleaned-up mid-stream" specimens are, however, relatively satisfactory as an index of infection of the bladder and higher parts of the urinary tract. When collecting a mid-stream specimen the urethral meatus should be washed, the first 20 c.cm. of urine passed into any vessel, and the remainder of the bladder contents passed straight into a sterile container.

Catheters are essential for obtaining representative bladder specimens if there has been antecedent gonorrhœa or prostatitis, and it is advisable to use a catheter in all males over the age of 50, owing to the frequency of mild chronic *B. coli* infections of the prostate. When examining for tubercle bacilli the specimen should always be taken with a catheter.

Females.—The cleaning up for bacteriological purposes of the external genitals of the female is difficult, and it is still more difficult to ensure that the urine is not contaminated with the numerous and varied vaginal and vestibular bacteria. Pus, epithelium, blood and mucus, all derived from the genital passage, are frequently present in the urine, and very few ordinary specimens of female urine are sterile on cultivation. Practically no reliance can be placed on the presence of pus and bacteria as indicating infection of the female urinary tract unless the specimen has been obtained with a catheter.

Children and Infants.—It is possible to catheterise even the smallest infant, but the procedure is not desirable when it can be avoided. Examination of a cleaned up specimen should always precede the passing of a catheter. Infants frequently pass water soon after they begin to feed. With patience a reasonable specimen of urine, uncontaminated with fæces, can be caught in a clean chamber if the infant is supported on the vessel held between the knees of the mother or nurse.

Ureteric Specimens.—When bacterial infection has been definitely located to the kidney it is frequently necessary to determine whether one or both kidneys are involved. This is particularly so in the case of tuberculosis. Ureteric specimens are best obtained with ureteric catheters passed by direct vision through a cystoscope—an operation requiring considerable practice and skill if injury to the ureter is to be avoided.

The Results of Preliminary Examination.

Examination of the urine for evidence of pyelitis is well worth while in all cases of fever of unknown origin, particularly in children, and in all cases of abdominal pain in which the diagnosis is at all obscure. The practitioner himself can rarely afford the time to do more than simple chemical tests for pus and blood, and examinations of the centrifugalised deposit or the deposit on standing.

The presence of pus in the urine can only be established with certainty by microscopical examination. Other methods, such as the caustic potash test or the ozonic ether test, only give positive results when much pus is present and they are in no way specific. Similarly, the guaiacum test for blood is extremely insensitive when compared with detection by the microscope. A simple microscope with a 1/4 in. and 1/6 in. objective is all that is needed in the majority of cases for obtaining evidence of bacterial infection, though a determination of the nature of the infection usually requires more elaborate apparatus and a more lengthy procedure.

---

* The significance of the type of organism present will be discussed next week.

Macroscopic Appearances.—Urine containing a large quantity of pus and bacteria has, when first passed, a characteristic sheen, whilst the turbid part rapidly settles to the bottom of the container in contrast to the slower deposition of amorphous phosphatic or uratic material. Though such an appearance is fairly characteristic the nature of the deposit should always be confirmed with the microscope.

Pus with Gonococci.—The macroscopic appearance of the urine is often used as a rough test of the state of the urethra and prostate in male gonococcal infections. For this purpose the urine is passed into two glasses, the first glass being an index of the condition of the anterior urethra, and the second glass that of the prostatic urethra. Obvious pus in the first suggests anterior urethritis, whilst "threads" or "commas" indicate that the prostate is involved. The procedure is sometimes elaborated by massaging the prostate before the urine is passed, so that the specimen contains prostatic secretion which can be concentrated with the centrifuge and examined for gonococci. This method yields less information than can be obtained from a stained smear of the prostatic secretion itself. It should always be borne in mind that pyuria in the male is not synonymous with gonococcal urethritis and that the continued presence of pus in the urine of a gonococcal patient merits investigation of the upper parts of the urinary tract.

Microscopic Appearances.

A drop of the urinary deposit is placed on a slide, covered with a slip and examined with the 1/4 in. and 1/6 in. objectives. A knowledge of sizes is of invaluable assistance in differentiating pus cells, epithelial cells, and red cells one from another or from foreign material such as droplets of oil derived from a catheter. Crystals and casts require more experience, but the commoner crystals, such as calcium oxalate or uric acid, and the general form of a cast can quite easily be recognised. Practitioners rarely find it an economical procedure to maintain a stock of bacteriological stains or a 1/12 in. oil immersion objective. When stained preparations are made, Gram's method with a suitable counterstain is the only reliable technique. Simple methylene-blue stained smears are useful as a guide, but in definite *B. coli* infections the bacilli can be seen with the 1/6 in. objective in an unstained preparation.

The practitioner, with his own microscope, can frequently find some evidence of urinary infection, though the exact nature of the infection usually requires a more elaborate investigation by a laboratory. Periodical examinations by the practitioner serve as a check on the progress of the more acute and definite infections, but it should be realised that any test, other than a cultural one, is almost valueless for estimating a cure.

THE EVOLUTION OF HOSPITAL SCHOOLS:

COMBINED TREATMENT AND EDUCATION FOR CHILDREN SUFFERING FROM PHYSICAL DEFECTS.*

BY SIR HENRY GAUVAIN, M.D., M.CHIR. CAMB., F.R.C.S. ENG.,
MEDICAL SUPERINTENDENT OF THE LORD MAYOR TRELOAR CRIPPLES' HOSPITALS AND OF THE MORLAND CLINICS, ALTON;

AND

EVELYN M. HOLMES, M.B. MANCH.,
RESIDENT MEDICAL OFFICER, MORLAND CLINICS, ALTON.

THIS paper is designed to call attention to a movement which has almost imperceptibly gathered force and momentum during the last 20 years, is still increasing rapidly, is changing and is still further destined to change the whole outlook and future of the physically defective child of the elementary school type. While familiar to some social workers, educationists, and others especially interested, its importance is as yet hardly appreciated or understood by the general public. It is especially desirable that it should be recognised by and secure the support and sympathy of the medical profession, as it is a matter which is primarily dependant on expert medical help and guidance.

While much of what follows refers to the crippled child, we would urge that the term physically defective in this connexion should not be confined to the cripple, but rather be extended to embrace all those children, other than the mentally defective, who show pathological deviations from the normal of such a degree as to make desirable special provision for combined medical and educational treatment, whether temporary or prolonged.

And here let us emphasise that the first and essential responsibility for the management of such children rests, not with the teacher but with the doctor. Children may be divided into two broad groups: those who are well and those who are not. For the latter, every endeavour should be made to achieve restoration to normal health whether the disability be of short duration or chronic in type. One would imagine such a statement to be self-evident. In acute illness it is accepted, but in chronic disability it is not. It is our purpose to direct attention to this matter, and we feel that prolonged experience in the management of the disabled child is not only a justification for a plea on his behalf, but also a responsibility which makes such a plea necessary.

The Chronically Disabled Child.

For the chronically disabled child of the working-class parent we shall proceed to show that almost nothing was done in the way of combined treatment and education until the present century; but during the last 30 years the outlook for such children has undergone revolutionary and beneficent changes. For other children, there is little advance to be recorded. For the secondary or public school child, on the other hand, there is no State aid, no guiding organisations, almost no specially staffed and organised institutions—no corporate life with its wider outlook, its spur to ambition, its competition, its scope for achievement and advance, its morale and discipline, its inviting threshold to active and useful adult life, with all its opportunities and responsibilities. The greatest bar to their progress is the inability through lack of knowledge of their parents to realise their children's potentialities and how they may best be catered for, and the lack of opportunity of obtaining the necessary help. The more severe cases are usually tenderly cared for in their own homes, shielded from those stimulating influences which should so improve their character and moral fibre, and denied the opportunity of exercising those gifts of aptitude and intelligence with which, as a rule, they are richly endowed. The less severe cases attend day schools perfunctorily or are drafted to so-called schools for delicate children. A few struggle through ordinary schools, but handicapped by afflictions which might often be remedied, do not get their full chance and, their sensitive natures exposed unhappily too often to the derision and scorn of their schoolmates, stand grave risk of being warped and soured. A schoolboy or girl may often unthinkingly be a little beast to his afflicted fellow. How many of us realise the sufferings of the unhappy victim of nocturnal enuresis in the ordinary school? And that is a comparatively trifling example. This is deplorable, as the potentialities of these afflicted children are immense, both to the community and to the individual. Their very defects may not infrequently in skilled hands be turned to advantage. A very real effort should be made on their behalf.

---

* A paper read before the Medical Officers of Schools Association on March 15th.

Historical Survey.

One of the most profound changes which has taken place in English elementary education during the last 20 years has been the direct attention given to the physical condition of the child. It has gradually been realised by school authorities that each child must be dealt with as a growing individual whose mental capacity and development is dependent on his health and physical fitness. Taking first and chiefly the cripped child, throughout history his has been an unhappy lot. The Spartans with eugenic motives took their cripples to the hill tops and killed them.[1] The Athenians allowed theirs to die from cold and neglect.[2] Similar treatment has been common amongst many savage races with less justification. In mediaeval times in our own country the cripple was coupled in men's minds with malignity. It was assumed that the crippled in body were crippled in mind too; and they must often have become so as a result of the attitude of others to them. As Sir Robert Jones has said:

> "Just as the mediaeval witch became obsessed by the enshrined belief in her own devilment, so the cripple, taunted, shunned and persecuted, found refuge in a mind as distorted as his body. This perversion of character, as familiar in Shakespeare's 'Richard III.,' as in Dicken's 'Quilp,' or Hugo's 'Hunchback of Notre Dame,' presents the bitter revolt of men in exile and contempt."

Where such ideas did not predominate, the attitude was one of ridicule. The hunchback was chosen to be the jester of the court. With the Reformation crippling deformity was considered emblematic of heavenly wrath, and the cripple was cast more completely than ever from the pale of society. Nevertheless, in innumerable instances throughout history cripples, in spite of their physcial disabilities, have achieved distinction and exercised important influence.

The first legislative provision for cripples which we can trace was in 1601 when custody only for cripples was allowed by the Poor Relief Act. When attention was being drawn generally to child welfare during the industrial revolution of the nineteenth century interest became rather more concentrated on the cripple. But he was then regarded as a mere object of pity. Charles Dickens aroused interest by depicting very truly the attitude of the public in his day to the cripple and the attitude of the cripple, perforce, to himself, with no thought or hope of cure; but a more or less cheery philosophy and acceptance of his inevitable fate. It was generally understood that if they survived, their deformities were likely to render them useless as citizens. Cases congregated in homes for incurables and workhouse infirmaries, or were hidden in the recesses of their own homes with no books, toys, or interests. Here and there a philanthropic worker would make some effort to give them help and add to the interest of their lives. An early pioneer was Lord Shaftesbury, who did so much to win the sympathy and help of the public for these unfortunate children.

In 1851 and 1865 two industrial homes were founded for older cripples which are still in existence. The one was the Cripples Home and Industrial School for Girls in Marylebone (now transferred to Winchmore Hill), and the other was the National Industrial Home for Cripple Boys at Kensington.

When the Education Act of 1870 made elementary education compulsory no cognisance was taken of children who by reason of mental or physical defect could not attend or profit by ordinary school. During the 10 years preceding the beginning of the twentieth century a few efforts were made by individuals to start little schools for some of these crippled children and the Board of Education, as an act of grace, allowed them to rank as infants schools for purposes of grant.[4]

The first real move for the cripple, however, was taken by Mrs. Humphrey Ward. She made use of the Passmore-Edwards Settlement off the Gray's Inn-road, which had existed as a play centre, and with the help of friends on the London School Board opened in 1899 a small school for 25 invalid and crippled children. This was the first day school for physically defective children to be supported out of public rates.

In 1893 the first step had been made in specific legislation for defective children by the Elementary Education (Blind and Deaf Children) Act enabling local education authorities to deal with children of this category in their area. Cripples were left out simply because it had never occurred to persons in authority that they merited consideration. Mrs. Humphrey Ward, with the support of the committee of the Passmore-Edwards Settlement and the newly gained interest of the London School Board, then urged the extension of this Act to include other defective children. The passing of the Elementary Education (Defective and Epileptic Children) Act of 1899 was a result of this, and for the first time gave statutory power to local authorities to deal with the education of the cripple child. Though permissive only, it gave them the power to make arrangements for ascertaining what children in their area were suffering from such physical defects as made them incapable of receiving proper benefit from instruction in the ordinary elementary school, and for providing for the education of such children. The first day school for cripples, to be certified under this Act, was this Passmore-Edwards Settlement School, which was certified in 1900. The first residential cripple school to receive official recognition was the Heritage School of Arts and Crafts, Chailey, Sussex, founded and conducted by Mrs. Kimmins. In 1905 the Manchester Education Committee established the first municipal residential school for physically defective children at Swinton House.

Such developments are of special interest when one recollects that it was not until 1907, by the Education (Administrative Provisions) Act, that the School Medical Service was inaugurated. This is the most important landmark in legislative attempts to improve the lot of the physically defective child. Under the wise, statesmanlike, and sympathetic guidance of Sir George Newman an entirely new era was opened for the defective child, and while much still remains to be done, almost incredible advances have been made with incalculable benefits both to the individual and the community.

No immediate measures followed this Act. For financial reasons local authorities were encouraged rather to coöperate with voluntary agencies than seek assistance from the Board of Education on behalf of the debilitated crippled children in their areas.[5] But all the time public sympathy was being further enlisted and public opinion educated to the needs of the debilitated and crippled child.

The Experiment at Alton.

In September, 1908, the Lord Mayor Treloar Hospital and College was opened in the derelict Princess Louise Military Hospital at Alton. Sir

William Treloar was a philanthropic but shrewd man of business. Inspired by Charles Dickens' "Christmas Carol" to help cripple children, he had inaugurated some years previously a crippled children's Christmas Hamper Fund. He soon realised what a small proportion of the physically defective children of the metropolis were receiving adequate medical attention. Country hospitals for such patients were unknown. No institution existed which combined expert medical aid, education, and technical training. Treatment in the few cripples' homes was either non-existent or so notoriously bad that the term cripples' home was associated with pity and contempt. Orthopædists had not even considered the wider and essential issues of combining with adequate treatment, education, and technical instruction. Philanthropists who were interested in cripples took for granted that surgical skill could do so little that provision for specialised treatment was hardly called for, and the cripples' home was a mere asylum for sheltering the unfortunate recipient of its charity.

The scheme originated by the late Sir William Treloar is still the most perfectly adapted to the full needs of the cripple child with which we are acquainted. Briefly, it comprises the treatment of the cripple by the most modern orthopædic methods with preference to conservative treatment in surgical tuberculosis, in an open-air country hospital situated in a specially suitable locality. In addition to specialised methods of local treatment the importance of rest, exercise, open-air, and sunlight has been recognised and utilised to the full from its inception. To these have been added artificial light treatment since 1912 and sea-bathing for therapeutic purposes since the establishment of its seaside branch at Hayling Island immediately after the late war. During treatment, and since the foundation of the hospital, children have received education, and this without grant from the education authorities for the first five years of its existence. From its inception there has been practised a carefully planned system of after-care designed on the broadest medical and social lines.

For the adolescent cripple, for whom further surgical aid could not be given, technical training combined with specialised education in a separate institution, but under the same management, has been employed from the outset. Boys admitted to this department of the hospital's activities—the College—receive training for three years in a trade suited to their limitations. On completing their training they are assisted to find permanent employment. By means of an old boys' association contact with them is maintained after discharge and they are helped and encouraged by every possible means and assisted to fresh employment if and when required.

After the passing of the Act of 1907 progress became more rapid. By the Finance Act of 1911 £1,500,000 was put aside for sanatorium work and the like, both children and adults benefiting.[6] In 1912 further grants were given. In the same year pulmonary tuberculosis became notifiable and this helped to diminish infection and trace more easily cases of surgical tuberculosis. Meanwhile 92 day and residential schools for the education only of cripple children had been established accommodating 4617 children and certified as "special schools" by the Board of Education. Fifty-five of these were receiving an annual grant from the Board.[7]

It had been realised already that prolonged treatment was advisable in special sanatoriums under constant expert medical supervision for children with acute tuberculous infections of the bones and joints and that stay in sanatoriums was advisable until complete arrest of the disease had been secured, a period often of 18 months to two years, or even longer. Yet not in one case in special school or in hospital had education and treatment coexisted officially. The Lord Mayor Treloar Hospital, however, at Alton, had, as already stated, on its own responsibility and from its inception in 1908, been offering educational facilities to its patients.

Under the Elementary Education (Defective and Epileptic Children) Act of 1899 the hospital was certified as a "special school" for 40 life-children in May, 1913, when two qualified teachers were appointed. These teachers took charge of the convalescent children who were taught in the school-room or the forest school. The Chief Medical Officer in his report to the Board of Education for 1912, having sketched the above, continued as follows:

> "The medical superintendent and the trustees, however, were desirous that the arrangements for teaching should be extended so as to provide for children who were still confined to bed. In view of the special circumstances, and in order to overcome the difficulty of introducing effective ward-teaching into an institution which is primarily a hospital and not a school, the Board agreed to sanction an experimental scheme. Under this scheme the school was to be certified for 150 children and the staff to consist of four fully qualified teachers."[8]

And the report concluded with a remark on the difficulty of grafting such an educational scheme on to existing hospital arrangements, as if it was very conscious it was venturing on untrodden ground, and emphasised the necessity of sympathetic coöperation and give and take between the nursing and teaching staffs. This, then, was the first "hospital school," the first recognised attempt to cure and educate the cripple at one and the same time.

Lord Melchett, then Sir Alfred Mond, Minister of Health, speaking at Alton in 1922, referred to this as follows:

> "Sir George Newman had just reminded him that when the Prime Minister visited the (Treloar) hospital in 1911 he was so struck by the important work being done there that he then and there decided to start the giving of grants to make it possible for the work done there to be extended throughout the country. The hospital was a great monument and was a milestone on the road leading to the increased *care and welfare of children.*"[9]

Changing Outlook for the Cripple.

The importance of this official recognition and approval will be readily realised. Other hospitals soon followed and within a year Heswell, Woodlands (Birmingham), and Leasowe (Cheshire) were also approved by the Board for purposes of grant. Gradually but surely the outlook of the cripple, notably the tuberculous cripple, was changing. But with the general public, even among educated people, crippledom was still considered a condition which did not merit much attention, it not having been realised that the cripple could be of any appreciable economic value to the nation. Where the local authorities had attended to the education of the crippled child in their area this was in the vast majority of cases arranged for in schools for the mentally defective. This is so even now in some areas. The blind, the deaf, the epileptic, and the mentally deficient were earlier and better catered for than the cripple. Indeed, when in 1914 the *Amended Elementary Education (Defective and Epileptic Children)* Act was passed putting a duty on the local educational authority to make suitable provision for the education of mentally defective children over 7 years of age, no thought was taken of the cripple child for whom as yet no compulsory measure had been passed by Parliament.

Then came the war with its inevitable toll of crippling among the adult male population. In the words of Sir William de Courcy Wheeler:

> "The success which followed the stupendous effort of the medical profession and its allies to restore maimed and crippled soldiers to a normal condition of useful citizenship awakened Britain and America and most of the civilised world to the fact that crippledom amongst the civil population was an unnecessary and avoidable evil."[10]

At the same time "returns" from cripple schools were showing that 70 to 90 per cent. were being discharged fit to compete in the ordinary industrial life of the nation. The cripple, hitherto a menace to society, was being proved capable of taking his own stand in the world. In other words, his combined treatment and education were worth while. The

London Education Committee Return for Cripple Schools in 1917 states that :—

Concerning 1609 children leaving 36 certified day schools in the three years ending March 31st, 1918 :—

Passed out below 14 as physically fit to attend ordinary public elementary schools	345
Exempt at 14 as being no longer physically defective ..	94
Exempt between 14 and 16 for suitable work	768
Left school at 16 because of age limit (of these 70 per cent. fit for suitable work)	366
Obtained scholarships in various technical and commercial schools	36
	1609

In 1918 the Amended Elementary Education (Defective and Epileptic Children) Act of 1914, already alluded to, was extended to include the physically defective. It required the local authority to ascertain what children in their area were physically defective or epileptic and to make provision for their education as per Section 20 of the Fisher Education Act. Actually this section of the Act did not come into operation until 1926 and even now is not strictly enforced.

Meanwhile, however, from various reports it soon appeared that ½ to 1 per cent. of children of school age were requiring treatment and education as cripples —i.e., 30,000 to 60,000.[12] Investigations into the causation of crippling defects in school-children brought out a number of interesting points. Diseases of bones and joints (mostly tuberculous), infantile and other forms of paralysis, congenital defects, rickets, and accidents were chiefly responsible. Rheumatism rarely produces joint disease and crippling amongst children, though amongst adults the toll is high. Tuberculosis headed the list as an individual cause in children, and in order of frequency spine, hip, knee, and ankle. Poliomyelitis followed closely.[13] It is noteworthy that the age of onset for all types of crippling falls predominately in the years preceding ordinary school life; for the majority of cases of tuberculosis arise between the ages of 1 and 6, and of poliomyelitis the same, while rickets is essentially a disease of the first year or so, and congenital defects must also be included. As these figures of the early onset of crippling deformities were brought to light and as many years of medical inspection showed that a proportion of 30 to 40 per cent. of children on entering school at the age of 5 require medical treatment for various causes,[14] largely a result of neglect, new regulations were passed under the Education Acts of 1920 empowering local authorities to provide educative treatment and therefore medical supervision from the age of 2 upwards.

The importance of the physical, social, and general welfare of children of pre-school age had long been realised. Nursery schools for such children had been inaugurated by voluntary enterprise some years previously, and by the Education Act of 1918 their establishment and promotion had been officially recognised and grants provided in their aid. This later work on the age of incidence and causation of physical disability gave fresh impetus to the movement on their behalf, and an earnest attempt was made to correlate for them the work of the various health, educational, and general welfare organisations. By 1926 there were 99 day nurseries for 3354 children and 26 residential nursery schools with accommodation for 1367, but the greater number of these were still dependent on voluntary committees.[15]

These schools by overcoming the effects of the too-frequently insanitary and mentally and physically unhealthy environment of the homes from which many of the children come; by encouraging the natural unrestricted development of the children's mental and physical resources, whilst instilling appreciation of the principles of healthy living, of fresh air, wholesome food, and regular hours; and by the additional benefit gained by the modicum of discipline and education given, have proved indisputably their very great value and their promise.

At the same time as this legislation was being extended to provide for the older child with physical debility, as already stated, technical training for the adolescent cripple had been commenced as early as 1851, and such training combined with treatment was started at the Treloar College in 1908. These efforts were recognised officially in 1911 but the legislation was now further extended, giving opportunity for comprehensive schemes for vocational training on various lines with substantial provision of grants.†

Incidence of disability as it occurs amongst elementary school-children is well shown by Dr. (now Sir William) Hamer's report on this in the London area in 1919 as follows:[16]

Pulmonary tuberculosis	1,614
Surgical tuberculosis	3,507
Other crippling defects	5,407
Heart crippling	2,291
Delicate or otherwise unsuitable for ordinary school ..	17,228

To the Chief Medical Officer of the Board of Education it appears that the child who is in a chronic state of subnormal health now constitutes one of the most serious problems of the School Medical Service.[17]

SCOTLAND.

(FROM OUR OWN CORRESPONDENT.)

Aberdeen Joint Hospital Fund.

THE Aberdeen Joint Hospital Fund of £400,000 is now closed. This is not only a personal triumph for Lord Provost Lewis, but a great achievement for the north-eastern region of Scotland. It has taken only two years to raise this sum. In the last month Lord Provost Lewis called for £30,000—that is, £1000 a day —and he got it! He has done even better, for he took up a friendly bet of £5000 that he would not get his last £30,000 in a month. The bet has been handsomely paid and this £5000 has been added to the £400,000. With this and certain other subscriptions there is now some £7000 more than the total asked for. The story of this fund is a romance of generosity. Lady Cowdray began it two years ago with £25,000; Viscount Cowdray gave another £25,000, and two similar gifts from Sir Thomas Jaffrey and Sir Robert Williams completed the first £100,000, but there have been shoals of small subscriptions and the whole north-east of Scotland was roused to a great effort. Of the total, it is expected that £107,000 will go to endowment.

The whole scheme is now safe, and Aberdeen now leads Scotland on two issues—by the coördination of its public medical services and by the splendid impulse given to the voluntary hospital movement.

Scarlet Fever Antitoxin.

Dr. C. Barclay Reekie, medical officer of health for Dunfermline and medical superintendent of West Fife Joint Hospital, records his experience in a considerable epidemic of scarlet fever, where the overcrowding of the hospital during the winter months had been considerable. He states that they emerged without one fatal case, and attributes this largely to the use of scarlet fever antitoxin. "Its routine use," he is reported as saying, "had undoubtedly diminished the average length of stay of scarlet fever patients in hospital, and on many occasions during intensive overcrowding it was only its employment that made the admission of fresh cases at all possible. At first it had been thought that the expense of using antitoxin might not be justified, in view of the fact that scarlet fever did not endanger life to the same extent as did diphtheria; but experience had made it quite clear that they had an invaluable remedy, which, if used early in the disease, would prevent complications and greatly shorten the period of disability. The duration of residence now attained was the lowest on record, and there was no doubt that a saving had been effected in the cost of board of patients which more than covered the additional expense entailed. Furthermore, there had been a reduction in permanent disability resulting from complications of the disease." The experience in Scotland was summarised in the Board of Health annual report for 1927, and Dr. Reekie's clinical data are in line with observations elsewhere. But scarlet fever immunity is not a simple problem and it is too early to formulate definite conclusions. This experiment, however, in a small provincial hospital, is an indication of how rapidly the new ideas in public health are being applied practically. Over 30 years ago clinical experiment had begun with diphtheria antitoxin; but diphtheria is still with us in somewhat larger numbers than before, and the conquest of scarlet fever is not likely to be more rapid.

Influenza Vaccine: An Edinburgh Experiment.

This year Lieut.-Colonel W. Glen Liston, at the laboratory of the Royal College of Physicians of Edinburgh, has had the opportunity of testing the effects of influenza vaccines. The results, though important as far as they go, are not conclusive, and Colonel Liston does not regard them as more than the beginning of an investigation. In the recent epidemic 700 Edinburgh people were inoculated with a vaccine prepared almost on the lines of the vaccine recommended by the Government in 1918. The chief difference was that it contained more of the influenza bacillus than the 1918 vaccine. Its object was to vaccinate persons against both influenza and its complications. Colonel Liston had to depend on volunteers. In some cases whole staffs submitted to vaccination, but in other cases only a few. As the epidemic was in progress no time was allowed for the vaccine to produce immunity before exposure. As a preventive measure, therefore, the experiment had little chance of succeeding. But those vaccinated, and afterwards contracting influenza, seem to have suffered far less severely than the unvaccinated.

The results obtained in the case of the scavenging staff of Edinburgh Town Council, which are tabulated below, bear this out:—

	Vaccinated.	Not vaccinated.
Total of outdoor staff, 990 ..	139	851
Off work with influenza	13	78
Total number of days off	136	1096
Average days off per man	10·46	14·05
Percentage attacked	9·35	9·16

The important points to bear in mind are that in the case of the unvaccinated the period of sickness was longer, and that influenza attacked both classes in practically the same proportion.

The figures in this table are supported by figures obtained in connexion with a business house in the city. Of its staff 51 were vaccinated and 140 were not vaccinated. Out of the 140, 9 had influenza; out of the 51, 5. But while the attack lasted many days in the case of the former, it lasted but two days in the case of the latter.

PUBLIC HEALTH CONGRESS IN ZURICH.

To the Editor of THE LANCET.

SIR,—The preliminary programme for the 1929 Zurich Conference of the Royal Institute of Public Health, May 15th–May 20th, has now been issued and a copy can be forwarded on request. We are assured of the most cordial welcome by the Swiss National Government, the authorities of the Canton, City, and the University of Zurich, and by the leaders of the medical school of Zurich.

Invitations have also been received to visit various health stations in Switzerland. The Government gives a concession of 50 per cent. on the State Railway; free transportation will be provided on the Rhaetian Railway, Chur to Davos, and on the railways, Chur to Arosa, Sierre to Montana, and Aigle to Leysin. The local authorities at each of these well-known centres are most anxious to welcome as many members of the Congress as possible. We are further assured by the Czecho-Slovak Minister, Mr. Jan Masaryk, of a hospitable reception for those who may find time after the Congress to extend their journey to the two great Czecho-Slovak spas of Carlsbad and Marienbad.

In order to complete arrangements for the comfort of members of the Congress desiring to participate in the extensions it is essential that we should know immediately which of the visits members will desire to take. Particulars regarding the extensions and the routes to be traversed, together with information as to the expenses to members of the Congress, will be forwarded on application; non-members may accompany members, but will not be able to enjoy all the special privileges. The inclusive cost of the visit to the Congress at Zurich will range from £10 4*s.* 6*d.* for the short sea route, second-class travel on the Continent and hotel accommodation, to £12 12*s.* 6*d.* for first-class travel throughout and hotel accommodation.

Full particulars regarding the different extended journeys available after the Conference, together with a list of the various hotels in Zurich, is available on demand, and it is earnestly desired that all who propose to attend the Conference will communicate with us as soon as possible.

We are, Sir, yours faithfully,
E. W. HOPE, O.B.E., M.D., B.Sc.,
T. N. KELYNACK, M.D., M.R.C.P., J.P.,
Hon. Secretaries.

THE EMPLOYMENT OF BACTERIA IN MODERN WARFARE.

To the Editor of THE LANCET.

SIR,—Profs. Pfeiffer and Prausnitz are men of great scientific distinction who may be presumed to be competent to listen dispassionately to evidence, to examine it critically, and to give a true verdict. I ask them to bend their minds to this simple problem:—

In January, 1918, a laboratory attached to our 5th Army reported the isolation of bacteria, resembling bacilli of plague, from material dropped by a German balloon. This discovery is officially confirmed in our "History of the Great War." From this I quoted textually in my speech, and was therefore "sure of my facts."

No evidence to refute the official statement has ever been produced. There have been, it is true, vehement though vacuous denials by interested persons acting perhaps under instruction; but there is not one shred of evidence which has ever impugned the accuracy of our laboratory investigation. I therefore assume that my eminent colleagues must conclude, however reluctantly, that this discovery of bacilli is not open to doubt. I next assume that the hypothesis of spontaneous generation of bacilli has been abandoned. I venture, therefore, to summarise: the bacilli were found; they did not arise spontaneously; they must have been introduced into the material in which they were discovered; no one had access to this material before it was dropped in our lines, but units of the German Army.

Accordingly, I invite Profs. Pfeiffer and Prausnitz to rid themselves of prejudice, and after considering this evidence to join with all dispassionate people in passing a verdict of Guilty against the German Army upon the odious charge of employing bacteria as instruments of war.

I am, Sir, yours faithfully,
MOYNIHAN.
Portland-place, W., April 5th, 1929.

GALLOP RHYTHM.

To the Editor of THE LANCET.

SIR,—In the course of the interesting annotation on this subject that appeared in THE LANCET last week (p. 729) two types of gallop rhythm are said to have been described, whereof the one depends upon apparent reduplication of the first, and the other of the second cardiac sound. This is true, but the description perpetuates confusion.

In the *bruit de galop*, described by Potain, the first sound appears to be reduplicated and, whatever the explanation and significance, the rhythm is that of a galloping horse's hoof-beats: two sounds in rapid sequence, and a third after a definite interval. Only this sequence, which is that of a gallop, should be called galloping. What is wrongly spoken of as galloping rhythm, due to apparent reduplication of the second sound of the heart, is not a galloping rhythm at all, but that which C. J. B. Williams, 90 years ago, rightly called cantering rhythm, for the rhythm is that of a cantering horse's hoof-beats; one sound, an interval, and then two sounds in rapid succession. This sequence gives what the French rightly call the *bruit de rappel*. It recalls the heavy blow of a smith's hammer on the object being forged, followed by two shock-absorbing taps on the anvil.

Thus, apparent reduplication of the first sound is galloping rhythm, *bruit de galop* or (frequently) Potain's murmur. Apparent reduplication of the second sound may be called *bruit de rappel*, or cantering rhythm, but should never be called "gallop rhythm" for the best of all reasons—that it does not resemble the rhythm of a galloping horse's hoof-beats. The whole matter is admirably set out in a little book now insufficiently read—namely, Gee's Auscultation and Percussion.

I am, Sir, yours faithfully,
F. G. CROOKSHANK.
Wimpole-street, W., April 5th, 1929.

BLOOD STANDARDS.

To the Editor of THE LANCET.

SIR,—The inaccuracies in the ordinary blood count are well demonstrated by Dr. Dyke in your issue of March 30th (p. 681), and all pathologists will support him in requiring from instrument-makers a statement of what they mean by normal. The matter could well be carried further and a definite arbitrary normal agreed upon for all instruments.

The Haldane hæmoglobinometer is probably the most accurate in its method of comparing a sample with the standard scale, but unfortunately the latter is set far too high. In my experience the normal with this instrument ranges from about 78 to 85 per cent. and a reading of 100 per cent. is almost unknown. It is evident that a true reading can only be obtained by adding 20 per cent. to the Haldane figure. I believe this excessive standard to be chiefly responsible for the statement that the colour-index in pernicious anæmia is frequently below one and is of small value in diagnosis. The Tallqvist method is not as finely graduated as the Haldane, but I find that it gives a more reliable estimation because its standard is set nearer to what experience indicates to be the true normal.

The colour-index as at present rendered is of little value by itself. Thus an index of 1·1 in a red cell count of five millions indicates that the red cells are more or less normal, but the same index in count of two millions denotes serious derangement. I therefore suggest that the index be followed by the letter E (for erythrocytes) and a digit representing the nearest million of red cells in the count. In this way the first example would read 1·1(E5) and the second 1·1(E2), thereby giving a definite significance to the index.

I trust that the matter that Dr. Dyke has raised will not be allowed to drop, but that concerted action will be taken.

I am, Sir, yours faithfully,
C. E. JENKINS.

HICKMAN MEMORIAL FUND.

To the Editor of THE LANCET.

SIR,—A committee meeting of the Hickman Memorial Fund was held on March 27th, at which Lord Dawson presided. The possibility of fulfilling all the objectives of the appeal was fully discussed. It was decided that the Fund was, as yet, inadequate to restore Hickman's tombstone, to provide a memorial tablet for Bromfield Parish Church, to present a portrait to the Royal Society of Medicine, and to found a Hickman medal for original work of merit in anæsthesia. Subscriptions already received will be sufficient to deal with the three former, but not for the medal. In no better way can the object of this appeal succeed, both in honouring Hickman's name and in serving a useful purpose, than by stimulating research for new anæsthetics and methods, in which it must be admitted British anæsthetists have for some decades rather followed than initiated. The appeal will therefore not be closed for the present in the hope that some who have forgotten or overlooked the matter, or have not appreciated its practical as well as historical importance, and others who may feel that they are indebted to anæsthesia may yet give it their support. A list of subscribers will be published when the Fund is closed; Mr. V. Warren Low, F.R.C.S., 76, Harley-street, W. 1, is the hon. treasurer.—I am, Sir, yours faithfully,

CECIL HUGHES,
Hon. Sec.
London, W., April 3rd, 1929.

ACTIVE IMMUNISATION AND DIPHTHERIA.

To the Editor of THE LANCET.

SIR,—I was sorry and surprised to read in the paper by Surg.-Captain P. M. May and Prof. S. F. Dudley on this subject, published in your issue of March 30th (p. 656), that its two distinguished authors decided not to recognise as diphtheria the cases of the two boys, "the appearance of whose throats suggested a diagnosis of diphtheria," and from whose throats virulent diphtheria bacilli were isolated. Suppose these cases had occurred in a group of non-immunised boys, would they then have regarded them as only diphtheria carriers suffering from some other bacterial infection?

Other observers, such as those quoted by the writers, have recognised cases exactly similar to the two referred to above as cases of diphtheria; and in my opinion your two contributors are setting a bad precedent. I venture to say that the slightest attempt to gloss over a failure, however slight, will lead only to the discredit of the practice of immunisation which they are advocating.

I am, Sir, yours faithfully,
E. W. GOODALL.
Hemingford Abbots, Hunts, April 7th, 1929.

AN OVERDOSE OF THALLIUM ACETATE.

CONFLICTING REPORTS.

To the Editor of THE LANCET.

SIR,—It is interesting to note the conflicting reports regarding dosage and the metric system in this evening's papers when dealing with the thallium acetate case.

The *Star* says: "The strength of the solution, went on Dr. Scovell, was supposed to be 7·8 milligrammes to a drachm of body-weight."

The Evening News says: "Miss Tedham said there were 15·4 milligrammes in a gramme."

The *Evening Standard* says incidentally: "... That was based on the rate of 8·5 milligrammes per kilo body-weight," which may be correct.

I am, Sir, yours faithfully,
P. M. KEANE,
London, April 8th, 1929. Squadron-Leader, R.A.F.M.S.

⁂ A report of the inquest by our medico-legal *correspondent follows.*—ED. L.

MEDICINE AND THE LAW.

Overdose of Thallium Acetate: An Error in Calculation.

Dr. Cohen, the Wembley coroner, concluded on April 8th an inquiry into the death of three boys who *had been treated for ringworm at St. John's Hospital* for Diseases of the Skin, Leicester-square. The mother of the three boys described how they had each been given a draught in her presence at the hospital and how they had complained of pains later in the evening and next day and had died at different dates, which she gave. The hospital sister had told her that the medicine might cause the boys to complain of rheumatic pains; for this reason she had not called in a doctor immediately on their complaining of pain. Dr. Spencer Scovell, clinical assistant at St. John's Hospital, gave evidence that the drug used was thallium acetate, a recognised treatment for ringworm, the amount of the drug being based upon the weight of the child. The children had been weighed and the correct dose had been administered, assuming that the solution was of the strength she expected it to be. Asked by the coroner what was the lethal dose, she replied that a man was believed to have died, or very nearly died, *after drinking about a gramme of it.* The three boys should respectively have had 0·25, 0·23, and 0·18 gramme; that calculation was based on the rate of 8·5 milligrammes per kilo of body-weight. The drug was not dangerous if given in correct doses. Dr. R. M. Bronte and Dr. Roche Lynch gave evidence indicating that death was due to thallium acetate poisoning. Dr. Lynch said the bottle contained 5·6 times the quantity that was on the label. The hospital dispenser, a registered chemist, said she had qualified in July, 1926, and had been at the hospital since May, 1927. She produced the prescription which, as the coroner observed, required a mathematical calculation. Addressing the jury, the coroner said that Dr. Scovell had discharged her responsibilities correctly; it was no part of her duties to make the calculation to check the strength of the contents of the bottle. Thallium acetate, he continued, was a continental drug; the weights of it were worked out on the metric system and required to be converted from metric or decimal weight to apothecaries' weight. In this process a decimal was apparently misplaced; consequently the doses were increased tenfold in strength. The unfortunate error, he said, was one of calculation. The result was terrible, but, at the time *the mistake was made, the dispenser* was unaware of the danger of an excessive dose. The jury agreed that the three boys died from an overdose of the drug. The coroner then left to them the question whether what had happened was a mere mistake or whether negligence should be attributed to the dispenser for *having made the mistake.* "Before you can attribute negligence, you must make up your mind that she was not taking due care; this is a mistake in a mathematical calculation, not a careless pouring of a wrong dose from one bottle into another, or taking down a wrong medicine bottle." The jury found as their verdict that death was due to poison accidentally administered; they added a rider that there should be a better system at the hospital of checking weights and measures when making up prescriptions.

A solicitor who appeared at the inquest on behalf of the parents had asked questions which suggested that the treatment was exceptional; the parents' view seems to have been that they should have been specially warned that the drug was highly dangerous, so that they could have decided whether they should allow their sons to have the treatment or not. On this point the evidence of Dr. Bronte and Dr. Roche Lynch was that, though thallium acetate had not been *thoroughly investigated,* it was a recognised and indeed a common treatment. Similar questions were put on behalf of the dispenser in order to show that she might reasonably have been unaware of the danger of an overdose. The verdict of the jury, delivered after a careful and correct summing-up by the coroner, negatives any charge of negligence, and their rider will no doubt receive attention.

INFECTIOUS DISEASE IN ENGLAND AND WALES DURING THE WEEK ENDED *MARCH 30TH, 1929.*

Notifications.—The following cases of infectious disease were notified during the week:—Small-pox, 323 (last week 288); scarlet fever, 1919; diphtheria, 1053; enteric fever, 29; pneumonia, 2425 (last week 3578); puerperal fever, 47; puerperal pyrexia, 117; cerebrospinal fever, 20; acute poliomyelitis, 4; acute polio-encephalitis, 2; encephalitis lethargica, 20; dysentery, 7; ophthalmia neonatorum, 113. No case of cholera, plague, or typhus fever was notified during the week.'

Nineteen cases of small-pox were reported from the County of London—namely, Bethnal Green, 3; Poplar, 6; Shoreditch, 2; Southwark, 5; and Stepney, 3. In the vicinity of London an additional 52 cases were reported from West Ham, 1 from East Ham, and 1 from Ilford.

The number of cases in the Infectious Hospitals of the Metropolitan Asylums Board on April 2nd–3rd was as follows:—Small-pox, 163 under treatment, 6 under observation; scarlet fever, 1585; diphtheria, 1811; enteric fever, 9; measles, 98; whooping-cough, 1216; puerperal fever, 20 (plus 6 babies); encephalitis lethargica, 80; poliomyelitis, 4; "other diseases," 62. At St. Margaret's Hospital there were 15 babies (plus 8 mothers) with ophthalmia neonatorum.

Deaths.—In the aggregate of great towns, including London, there was no death from small-pox, 2 (1) from enteric fever, 71 (0) from measles, 9 (2) from scarlet fever, 153 (47) from whooping-cough, 41 (9) from diphtheria, 52 (10) from diarrhœa and enteritis under two years, and 536 (70) from influenza.

The number of deaths from influenza in London is lower than that for any week since that ending Jan. 19th, and the Registrar-General's chart shows that deaths from respiratory diseases in general have come down in almost the same ratio. The death-rate from all causes in the 107 great towns is now down to 17·0, Birmingham and Sheffield, which recently suffered so severely, showing rates of 14·9 and 13·9 respectively. The only towns still attributing a number of deaths to influenza are Bradford 26, Birmingham 24, Manchester and Sheffield 16 each, Bristol 15. Many of the Lancashire towns record 5 or more deaths from whooping-cough, including Warrington, Manchester, and Salford.

The number of stillbirths registered during the week was 311 (corresponding to a rate of 48 per 1000 births), including 67 in London).

Obituary.

SIR ANTHONY BOWLBY, BART., K.C.B., K.C.M.G., K.C.V.O.,

LATE PRESIDENT OF THE ROYAL COLLEGE OF SURGEONS OF ENGLAND; CONSULTING SURGEON TO ST. BARTHOLOMEW'S HOSPITAL.

WE deeply regret to record the death of Sir Anthony Alfred Bowlby, one of the most prominent figures in our world of medicine, both as a surgeon and as an administrator. The event occurred on Sunday, April 7th, at Stoney Cross, near Lyndhurst, at the age of 73, as a result of pneumonia.

Anthony Bowlby was the son of Thomas Bowlby, a Durham man, who was for a time a London solicitor, but who later led an adventurous life in the Near and Far East, and was on different occasions a special correspondent of the *Times*. Thomas Bowlby died in tragic circumstances in 1860 when in China on his journalistic duties. He was shipwrecked off Point de Galle, and then accompanied Sir James Hope, the English admiral, who was conducting the naval operations against China which followed the breach of the Tientsin Treaty. The conclusion of warfare resulted in the landing of troops at the mouth of Pehtang, and Hope went to Tientsin, where he remained till a treaty was signed in Pekin, but during the operations Thomas Bowlby was taken a prisoner, and died in captivity as a result of the treatment which he received.

SIR ANTHONY BOWLBY.

Photo by Elliott & Fry.

His son, Anthony Bowlby, was then five years old, and he was brought up by his mother, was educated at Durham School, and proceeded thence to St. Bartholomew's Hospital where he duly qualified in 1879 as M.R.C.S. England, proceeding two years later to the F.R.C.S. and filling the house appointments at the hospital. His career as a student was a distinguished one, for he gained many prizes as well as the Brackenbury Scholarship in Surgery. In due course Bowlby became curator of the St. Bartholomew's Hospital museum and completed the catalogue of anatomical, physiological, and teratological specimens, this work being afterwards summarised in his admirable "Students' Guide to Surgical Pathology." As curator he was noted for his intimate knowledge of the specimens and his excellent recollection of many of the clinical histories relating to them. In 1884 he became surgical registrar to the hospital and demonstrator of practical surgery, and in 1891 was elected assistant surgeon on the retirement of Sir William Savory. During his office as registrar he gained the Jacksonian prize at the Royal College of Surgeons of England with a dissertation upon the pathological symptoms and treatment of injuries to nerves, and a few years later he won the Astley Cooper prize with an essay developing the same themes. These two admirable pieces of work were later published in one volume, while in 1887 he delivered the Hunterian lectures at the College of Surgeons along similar lines. He had thus fully justified his election to the staff of the hospital, though he never happened to fill the post of demonstrator of anatomy which at St. Bartholomew's (as at many other of the metropolitan teaching schools) was regarded some 40 years ago as the regular precedent to a staff appointment. But certainly the character of his teaching did not suffer from the omission, for he speedily became recognised by the students as a clear, logical, and forcible instructor, and during the period which followed he built up by his solid work at St. Bartholomew's and at the Alexandra Hospital for Hip Disease a high reputation as an operating surgeon. His clinical teaching was that of a great demonstrator of patients, who combined wide knowledge with a close memory for pathological details. He had a knack of conveying a lesson in a manner that could never be forgotten, as the following extract from a correspondent's letter shows: "My first recollection of Bowlby is a piece of clinical teaching which bit into my memory and never faded. He was going round the wards when he came to a patient suffering from extravasation of urine. After demonstrating the case, he said, in his own inimitable, characteristic, slightly-guttural voice—for he had a little difficulty in pronouncing his 'r's'—'the right thing to do is to make a cut into it, even if you have only got a bit of old rusty hoop iron to do it with.' That sort of teaching was characteristic of the man: eminently practical, simple, and direct, couched in terms which make themselves remembered."

Bowlby's surgery was influenced considerably by Sir Thomas Smith and Howard Marsh, both of whom he had assisted for a very long time. He was never himself regarded as the finest of technicians, nor as a surgeon advancing any particular school of work; in fact, sometimes in his own hospital he was thought to be rather old-fashioned. For instance, he never adopted the method of treating carcinoma of the breast by the sweeping operations which came into vogue in the beginning of this century; he practised himself the smaller local excision, and it is interesting to note that the modern tendency of surgery is with him. His judgment was remarkable. He cared for his patients in every way; he kept them alive, and his opinion was sought always by his colleagues, so that he might have been described as the surgeon to their families.

In 1899 the South African war broke out and Bowlby went to the Cape as chief surgeon in charge of the Portland Hospital, and there laid the foundations of that knowledge of medical-military administration which he later used with such splendid success.

In a book entitled "The Civilian War Hospital" an account was given of the work of the Portland Hospital by Bowlby and the other members of the professional staff—namely, the late Dr. Howard Tooth, Mr. Cuthbert Wallace, Dr. J. E. Calverley, and Surgeon-Major C. R. Kilkelly, the P.M.O. of the hospital. Bowlby describes the sad opportunities offered to the staff to inquire first into the experiences of gun-shot wounds, and, secondly, into the characteristics of epidemic typhoid when the fever began to be serious at Modder River. Bowlby was particularly instrumental in removing camps rapidly from contaminated ground, and the result of his measures of prophylactic hygiene resulted in a remarkable change in the incidence of the fever. In another section of the volume Bowlby and Mr. Wallace (as he then was) give a succinct and detailed description of the surgical work of the war, especially of the surgical aspects of rifle fire, when the warning was issued that the gospel of the innocuous nature of bullet wounds had gone too far, and that there had been too great a confusion between the effects of the penetrating wound made by the projectile and penetrating wound inflicted by sharp instruments. For his services in the South African war Bowlby received the C.M.G. In 1904 he was appointed Surgeon to the Household of King Edward VII., and in 1910 Surgeon in Ordinary to King George, receiving a knighthood.

In 1914 Bowlby received the opportunity for which he was specially fitted. Being at that time a major in the medical branch of the Territorial Force he was attached on mobilisation of our army to the 1st London General Hospital, but his services at G.H.Q. were offered and immediately accepted, and he was appointed consulting surgeon to the Forces with the rank of major-general. The value of his work throughout the war is known to everybody. He became the type of the great medical administrator. He was hard-working, resourceful, clear, and bold. He radiated hope and confidence, while a certain simplicity and generosity of view transformed his abruptness of manner into tactfulness, this being especially displayed in his successful methods of removing friction between the regular and the temporary medical officers—indeed, it is not too much to say that the smooth working between them was largely due to his efforts. His familiarity with the conduct of military medicine gained in the South African war, and his knowledge of hospital administration acquired at St. Bartholomew's Hospital, made of him the ideal counsellor, while his advice always had the admirable backing of first-class professional knowledge. Frequent mentions in despatches were accompanied by the unusual distinction of three knighthoods, for in 1915 he was advanced to K.C.M.G., while in the following year he was appointed K.C.V.O., later C.B., and finally in 1919 K.C.B. In 1923 he was created a baronet.

Bowlby's connexion with the Royal College of Surgeons of England was a long and distinguished one. Winner of the Jacksonian prize and a Hunterian Professor, he was elected to the Council in 1904, and served on that body without break until 1920 when he was elected President in succession to Sir George Makins. He delivered the Bradshaw lecture in 1915 upon Wounds in War, in the course of which he summarised the first year's surgical work as Consulting Surgeon to the British Expeditionary Force in France, compared the conditions in South Africa and France, and described the character of the wounds inflicted by various projectiles with their effects on the tissues. "Nothing has impressed me," he said, "so favourably as the qualities of many of the younger surgeons on whom has rested the chief stress of the actual treatment of the wounded. . . . The care and zeal and patience displayed in efforts to save limbs and life have been no less praiseworthy than the operative dexterity." In this spirit Bowlby always regarded his juniors, and his words are quoted because they illustrate his unceasing aim to establish confidence and justify in the public eye the value that was attached by the high commands to the devoted character of the medical work.

In 1919 he was Hunterian orator at the College and did not experience any of the difficulties which many Hunterian orators must nowadays have in making their words both historical and topical. His address was delivered from the following text written by Hunter himself in relation to his work on bullet-wounds: "My appointment to the Belle-Isle Expedition drew my attention to inflammation in general and enabled me to make observations which have formed the basis of the present treatise." Bowlby proceeded to review military surgery from the time of Hunter in the eighteenth century down to the date of his Oration giving Hunter's and the famous Guthrie's views on primary amputation after gun-shot wound and showing how the percentage of saved limbs had steadily risen. He closed with a brief and clear description of the work of a modern casualty clearing station, showing that the war of movement which characterised the closing stages of the immense campaign just closed had called for the development of new methods. In every way the Oration was alive with topical information, and the audience felt that they were living the life described.

We have attempted to give a description of a great man of affairs, whose keen intellect and strong character showed through every action, while a quiet determination enabled him to carry out what he believed to be the right. For that describes the man.

Sir Anthony Bowlby married in 1898 Maria Bridget, daughter of Canon the Hon. Hugh Wynne Mostyn, and had three sons and three daughters. He is succeeded in the baronetcy by his eldest son, Anthony Hugh Mostyn, who was born in 1906.

ROBERT LAUDER MACKENZIE WALLIS,

M.D. CAMB.

Dr. Mackenzie Wallis, who died at Hove on April 1st, at the age of 43 years, was recognised as being in the front line of chemical pathologists. He had never completely regained his health since the serious illness three years ago when he gave up his general hospital work; his death was due to pneumonia and pericarditis following on extraction of some septic teeth.

DR. MACKENZIE WALLIS.

Educated at Downing College, Cambridge, where he took the natural science tripos in 1908, Mackenzie Wallis devoted himself at first to the study of chemistry, becoming a Fellow of the Chemical Society and demonstrating chemical physiology in the medical School at Cardiff under the late Prof. Berry Haycraft. He then completed his medical education at St. Bartholomew's Hospital, London, qualifying L.S.A. in 1913, and acting as surgical receiving-room officer before he resumed the work more congenial to him of chemical pathologist in the department of bacteriology. This work was interrupted by a period of war service, when he joined the staff of the Welsh General Hospital as temporary captain R.A.M.C. In India, where he was sent, his special merits were soon recognised, and he was seconded from the Corps as a research chemist to the Government of Bombay, where he worked on the purity of anæsthetic agents. Later on he investigated the diastatic output in trench nephritis with a view to elucidating its true nature. Returning at the end of the war he resumed his appointment at Bart.'s until 1926, when he joined the staff of the Children's Clinic, Western General Dispensary, and coöperated in investigations into the biochemistry of the nervous child, in whom he showed the calcium content of the blood to be materially reduced. As a lecturer and teacher of students he enjoyed a good reputation, for he had the essential faculty of stating intricate scientific facts in the simplest language. Side by side with his hospital work he developed a large private practice, in which his special chemical and biochemical knowledge was of great value. He worked particularly at skin sensitisation and the subsequent relief of the toxæmias so detected by the use of vaccines. Biochemical abnormalities in rheumatism, asthma, dyspepsia, and diabetes found in him a competent investigator and therapeutist, and patients came to him from all parts.

One of his colleagues writes: "Mackenzie Wallis was one of the most original thinkers in his branch of medicine. A large amount of routine work did not prevent his speculating on the significance of obscure facts and phenomena; it served him rather as a means for their elucidation. Although in some directions his fertile brain led him astray, in others he achieved a definite advance in work by which he will long be remembered. He was responsible for the hypothesis that the glycosuria of pregnancy is a manifestation of hyperpituitarism—a hypothesis which is now generally accepted. He correlated and defined the value of tests for pancreatic insufficiency; the methods now in routine use for the diagnosis of this condition are accepted largely as the result of his work on their mutual significance. He was responsible also for an original investigation into the pathogenesis of sulphæmoglobinæmia, the results of which indicated that this disease is due to the bacterial synthesis of a reducing substance in the gastro-intestinal tract.

"That Mackenzie Wallis was a tireless worker is sufficiently indicated by the wide field of his original work; that this should have been combined with routine institutional work and practice argued qualities which many must have envied him. His practice, especially in latter years, was a large one, and its success is the best indication of the opinion in which his patients held him. There is no doubt that beyond what he was able to do for them, he was liked by them for some more personal reason. Success in this direction is a thing for which the necessary conditions are hard to define, but the man who deserves it is certainly the man of goodwill and sympathy, and by this criterion Wallis's popularity may well be explained. His good nature was a quality by which all his colleagues will remember him, and he is one of the few men of whom it can be said that he never uttered a harsh word in speaking of anyone."

Dr. Mackenzie Wallis had a very happy family life and was a devoted husband. He leaves a widow and three children to mourn his loss.

ALEXANDER GRANVILLE, C.M.G., C.B.E., M.R.C.S. ENG.

Dr. Granville, who died in London on April 1st after a long and painful illness, had spent the active years of his life as a public health official in Egypt, where he reached the rank of pasha and maintained the high standard of work and conduct which characterised the administration of Cromer and Kitchener.

Alexander Granville came of a Huguenot family and was born at Brighton in 1874. His father died when he was still young, and the boy was taken with his three sisters to Florence, where he attended the day school of Mr. Domeugé, a French refugee, and learned to speak French and Italian fluently. His schooling was completed at Bloxham, in Oxfordshire, whence he entered St. Bartholomew's Hospital, qualifying in 1897. Failing to secure house appointments there for the moment he went on to the West London Hospital as house surgeon and house physician, returning to Bart.'s as resident assistant anæsthetist, a position of some responsibility and of special interest, as gas and oxygen was then just coming into use. While he was holding this post the South African war broke out, and Granville, who as a student had joined the Volunteer Medical Corps, took a commission in this regiment, and was captain before he sailed in 1899. He did good service in the war, obtaining the Queen's medal and three clasps, including Paardeburg; but he contracted enteric fever, complicated by phlebitis, and, returning to duty too soon; the thrombosis which resulted handicapped him throughout life, and was finally responsible for his death at the age of 55 from embolism. The obesity, which was also a legacy of this illness, was a heavy burden of which he made light. Having recovered from his illness he spent some time touring in the Mediterranean and up the Nile in Cook's steamers, and eventually joined the Egyptian army as civil surgeon, from which he was transferred to the public health department of the Egyptian Government. His work in Upper Egypt during the plague visitation of 1907–08 first attracted attention to his energy and administrative powers.

GRANVILLE PASHA.

In 1908, when he was 34 years old, Granville became medical officer of health in Cairo, one of the twenty largest cities in the world, and with a mortality unknown in Europe. A further opportunity soon came to him, for when the Cairo Municipality Section was formed at the Egyptian Ministry of the Interior, he was chosen as its first director, making so conspicuous a success in this post that when the complicated affairs of the Alexandria Municipality were the subject of an inquiry and a change in administration was advised he was appointed director-general there. In 1917 he succeeded Sir Armand Ruffer as President of the International Quarantine Board, a post he held till he retired. During the war, as President of the Board of Conciliation, he did invaluable work during the labour troubles in Egypt, and for his services was created pasha by King Fuad. He was also Red Cross Commissioner for Egypt, Palestine, and Syria from 1917. On retiring from the Egyptian Government service in 1923 his services were retained to attend the meetings in Paris of the Office International d'Hygiène Publique as representative of Egypt. His frequent attendance in Geneva was also required as head of the Egyptian Medical Mission to the League of Nations. It was on one of these journeys from Paris to Geneva that he had the attack of food poisoning which compelled him gradually to relinquish work, and for the last two years he was able to undertake very little.

Of the personal characteristics which led to a life so full of usefulness one of his friends writes: "Granville made a first-rate administrator because he had the faculty for getting things going, and had a charm of manner which made him popular with everyone from King Fuad down to the humblest peasant. He was a good judge of character, and his conversation was pleasant, kind, instructive, and whimsical. He was a fine linguist; his French was perfect, his Italian good, and of Arabic he had a good working knowledge: in any of them he could be witty.

"He had a keen and critical appreciation of many forms of art: painting and its allies, literature and music, good food and good drink. He wrote amusing letters to his personal friends, illustrating them with sketches and drawings in ink or water-colours, and his powers of burlesque were out of the ordinary. If he had not been a doctor he might easily have become a writer or a sculptor."

His honours were many. He was among other things a Knight of Grace of the Order of St. John of Jerusalem, Officer Legion of Honour, a Commander of the Order of the Crown of Italy, a Commander of the Order of George of Greece, a Commander of the Order of Leopold of Belgium, and a Commander of the Hachimite Order of the Nahda. He received the Second Class Order of the Nile (Egypt), and Orders of Medjidieh and Osmanieh (Turkey). His C.M.G. was granted for his sanitary work in Cairo and his C.B.E. for war work.

He married in 1921 Ierne Goold Adams, daughter of Assheton Biddulph, M.F.H., of Moneygwyneen, Birr, Ireland, who survives him.

WILLIAM LOUIS BYHAM, M.R.C.S. ENG.

THE sudden death of Mr. W. L. Byham on March 10th came as a shock to his many friends and patients in Sunbury-on-Thames and neighbourhood. He had been actively engaged in professional duties during the day on which he died.

Born in Ealing, Byham joined St. Thomas's Hospital as a medical student in 1879. After obtaining his qualifications, he spent three years as a medical officer on board ship, during which time he visited China, Japan, South Africa, and the West Indies. In this country he began practice at Spalding and worked there for seven years; afterwards he took a practice at Sunbury-on-Thames. In 1907 he was appointed medical officer of health to the Sunbury Council in succession to Dr. Palgrave, and amongst other appointments was medical officer to the Staines Union, the Post Office, the Metropolitan Water Board, and the Sunbury Orphanage. During the war he was medical officer to the large depôt of the Royal Army Service Corps at Kempton Park, and did much work for local members of the profession, who were called up for duty with the Forces. It is probable that the strain of this additional work caused his heart to become affected and made it increasingly difficult for him to carry the burden of an important practice, necessitating as it did response to unexpected calls at all times of the day and night, especially during the bitter weather of the past winter. A man of unusually good physique, Byham in his earlier life was known in Rugby football circles as a stalwart forward; he was also a good cricketer and all round sportsman. A colleague writes of him that "although a very busy man during recent years, he was never too much occupied to listen to the story of the poorest patients, and his thoughtful cheery manner endeared him to all with whom he came in contact."

Mr. Byham married in 1894 Miss G. Lamb, of Sunbury-on-Thames, who survives him; he also leaves a son and a daughter. The funeral service on March 23rd was largely attended by friends of all ages.

The Services.

ROYAL NAVAL MEDICAL SERVICE.

Surg. Comdrs. G. A. S. Hamilton to *Constance*; A. G. McKee to *Centaur*; and J. Kirker to *Victory*, for R.N. Barracks, Portsmouth.

ROYAL ARMY MEDICAL CORPS.

TERRITORIAL ARMY.

Col. G. A. Troup, having attained the age limit, retires and retains his rank, with permission to wear the prescribed uniform.

Capt. F. J. Morris to be Maj.

Capt. F. C. Hilton-Sergeant, R.A.M.C., to be Divl. Adjt. 42nd (E. Lan.) Div., and Sch. of Instn., vice Maj. B. C. O. Sheridan, R.A.M.C., vacated.

Lts. to be Capts.: A. H. G. Down, E. J. P. McDowell, and W. G. Saunders.

H. Baxter to be Lt.

Supernumerary for Service with O.T.C.: Lt.-Col. P. H. Mitchiner to be Bt. Col. and Lt. W. R. Martine to be Capt.

ROYAL AIR FORCE.

The undermentioned Flying Officers are granted permanent commissions: D. A. Wilson and F. E. Lipscomb.

Squadron Leader J. R. Crolius (retired list) is reinstated on the active list as a Squadron Leader.

Flight Lt. F. T. Boucher is transferred to the Reserve, Class D. ii.

Brendan Leo Harrington (temp. Lt., General List, Army, Dental Surgeon) is granted a temporary commission as a Flying Officer (Dental) on attachment to the R.A.F.

INDIAN MEDICAL SERVICE.

The undermentioned appointments have been made in India:—A.D.M.S.: Col. P. H. Henderson, R.A.M.C.; D.A.D.M.S.: Maj. R. A. Logan, I.M.S.; Dir., H. and P.: Maj. (Bt. Lt.-Col.) H. H. A. Emerson, R.A.M.C.; A.D.H.: Lt.-Col. A. C. Munro, I.M.S.; D.A.D.H.: Maj. F. C. Tibbs, R.A.M.C.; D.A.D.'s P.: Maj. C. H. K. Smith, R.A.M.C.; and Maj. R. N. Phease, R.A.M.C.

Capt. J. D. O'Neill retires, receiving a gratuity.

Temp. Capt. Chuni Lal Bhola relinquishes his temp. commn.

COLONIAL MEDICAL SERVICES.

Dr. T. W. H. Burne has been promoted to Senior Surgeon, Federated Malay States.

The following appointments have been made: Mr. F. McLagan, Alienist, Gold Coast; Lt. F. O. W. A. Mahon-Daly, Medical Officer, Nyasaland; Mr. R. E. Henderson, Mr. G. H. Henry, Mr. R. C. Jones, Mr. T. Simpson, and Capt. H. R. F. Tweedy, Medical Officers, West African Medical Staff.

DONATIONS AND BEQUESTS.—The late Mr. D. B. Ritchie, of Glasgow, left, subject to certain life interests, £2000 to the Glasgow Royal Cancer Hospital, and the remainder of his estate to the Glasgow Royal Infirmary, the Western Infirmary, and the Victoria Infirmary.

ALCOHOL IN THERAPEUTICS.—Addressing the Society for the Study of Inebriety on April 9th, Dr. J. D. Rolleston said that a remarkable decline had taken place within the last 30 years in the therapeutic use of alcohol. This was best illustrated by the fall in the alcohol bill in various hospitals and was also exemplified by the practice of individual physicians and the small place which alcohol now occupied in text-books of medicine. The low esteem in which alcohol was held as a therapeutic agent in the United States was shown by the fact that only a minority of practitioners applied for a licence in those States in which the right to prescribe alcohol was granted, while a considerable proportion of this minority used it for illicit purposes. Dr. Rolleston said that the conditions in which alcohol was still chiefly employed were pneumonia, enteric fever, diphtheria, and other acute infections, diabetes, heart disease, tuberculosis, senility, and inoperable cancer, but it did not appear to be indispensable in any of them. The experience at the Western Hospital, Metropolitan Asylums Board, of which he is medical superintendent, had shown that in an annual population of over 5000 patients the consumption of alcohol could be reduced almost to nil without any injurious effects. The factors chiefly responsible for the undeserved esteem which alcohol still enjoyed as a therapeutic agent appeared to be extra-medical influences, personal considerations, and tradition rather than scientific evidence.

Hampstead General and North-West London Hospital, Haverstock Hill, N.W.—H.S., Cas. M.O. Also Cas. Surg. O. Each at rate of £100.

Harefield, Middlesex, County (Tuberculosis) Sanatorium.—Third Asst. Res. M.O. £400.

Huddersfield Royal Infirmary.—Locum Pathologist. 12 guineas weekly.

Hull Royal Infirmary.—Cas. H.S. At rate of £130.

Liverpool City.—Asst. City Bacteriologist. £600.

London Female Lock Hospital, Harrow-road, W.—Hon. Obstet. Surg.

London Skin Hospital, 40, Fitzroy-square, W.—Hon. Dermatologist.

Manchester, Ancoats Hospital.—Res. Surg. O. £200.

Manchester Babies' Hospital, Burnage-lane, Levenshulme.—Hon. Ear, Nose and Throat Specialist.

Manchester Royal Infirmary, Central Branch, Roby-street.—Jun. H.S. £100.

Manchester, Salford Royal Hospital.—Res. Surg. O. At rate of £200.

Manchester, Victoria Memorial Hospital.—Sen. H.S. £250.

Metropolitan Hospital, Kingsland-road, E.—Sen. H.P. and H.S., Jun. H.P. and H.S. Also two Cas. O.'s. Each at rate of £100.

Miller General Hospital, Greenwich-road, S.E.—Out-Patient Officer. At rate of £150.

New Delhi, India, Lady Hardinge Medical College.—Prof. of Anatomy. Rs. 750 a month.

Northern Rhodesia, Roan Antelope Copper Mines.—Chief M.O. £2000.

Preston and County of Lancaster, Queen Victoria Royal Infirmary. Hon Asst. S. and Hon. Asst. P.

Prince of Wales's General Hospital, Tottenham, N. — Res. Sen. H.P. Sen. H.S. and Special H.S. Each at rate of £120. Also Jun. H.P. and Jun. H.S. Each at rate of £90.

Queen's Hospital for Children, Hackney-road, E.—Surg. to Ear, Nose and Throat Dept. Cas. O. At rate of £100. Also H.P. At rate of £100.

Redhill, Surrey, Royal Earlswood Institution.—Jun. Asst. M.O. At rate of £250.

Royal College of Surgeons.—Examiners, &c.

Royal Waterloo Hospital for Children and Women, Waterloo-road, S.E.—H.S. At rate of £100.

St. Andrew's Hospital, Dollis Hill, N.W.—Jun. Res. M.O. £120.

St. John's Hospital, Lewisham, S.E.—Res. M.O. £200. Also Res. Cas. O. and Jun. H.S. Each at rate of £100.

St. Stephen's Hospital, 369, Fulham-road, S.W.—4th Asst. M.O. £300.

Samaritan Free Hospital for Women, Marylebone-road, N.W.—H.S. At rate of £100.

Sheffield, Nether Edge Hospital.—H.P. £150.

Sheffield Royal Hospital.—H.P. Also Res. Anæsthetist. Each at rate of £80.

Southend-on-Sea, County Borough of.—Asst. M.O £600.

University College, W.C.—Bayliss-Starling Memorial Scholarship. £120.

Warrington Infirmary and Dispensary.—H.P. £150.

Westminster Hospital, Broad Sanctuary, S.W.—Asst. Surg. Reg. At rate of £50.

Wolverhampton Poor-law Institution.—Sen. Res. M.O. £600. Also Jun. Res. Asst. £200.

Wolverhampton and Midland Counties Eye Infirmary.—H.S. £200.

Wolverhampton, Royal Hospital.—Cas. O. and Res. Anæsthetist. At rate of £125.

The Chief Inspector of Factories announces vacant appointments for Certifying Factory Surgeons at Wolston (Warwickshire) and Irlam (Lancs).

Births, Marriages, and Deaths.

BIRTHS.

DODD.—On Easter Day, at the Red House, Dartmouth-grove, S.E., the wife of Dr. Frederick H. Dodd, of a son.

SHEPHERD.—On Easter Sunday, at St. Andrew's-crescent, Cardiff, the wife of Dr. C. W. Shepherd, of a daughter.

MARRIAGES.

MOORE—HOLT.—On April 4th, at St. Barnabas, Kensington, Frederick Craven Moore, M.D., F.R.C.P., of Victoria Park, Manchester, to Marjory, second daughter of the late Sir Edward Holt, Bart., and Lady Holt, of Manchester.

DEATHS.

ADDISON.—On April 3rd, at Worthing, very suddenly, Hugh Cecil Addison, L.R.C.P. Lond., M.R.C.S.

BOWLBY.—On April 7th, at Stoney Cross, near Lyndhurst, Sir Anthony Alfred Bowlby, Bt., D.C.L., K.C.B., K.C.M.G., K.C.V.O., F.R.C.S., aged 73 years.

DUHIG.—On April 3rd, 1929, at Heckmondwike, Yorkshire, after a very short illness, David John Duhig, M.D.Trin. Coll. Dub., Fellow Royal Society of Medicine; Hon. Assistant Aural Surgeon, Dewsbury Infirmary. Deeply mourned by his sorrowing wife and family. "Love outlasts death."—R.I.P.

GILLIES—On April 3rd, at Stafford-road, Southsea, J. W. F. Gillies, M.R.C.S. Eng., L.R.C.P. Lond., of Down-street, S.W.

VAISEY.—On April 2nd, at Combe Down, Bath, Thomas Frederick Vaisey, M.R.C.S.E., L.R.C.P., late of Winslow, Bucks.

WALLIS.—On April 1st, at Hove, Robert Lauder Mackenzie Wallis, M.D., of Harley-street, W., aged 43 years.

N.B.—A fee of 7s. 6d. is charged for the insertion of Notices of Births, Marriages and Deaths.

Notes, Comments, and Abstracts.

PITFALLS IN THE RIGHT SIDE OF THE ABDOMEN.*

BY H. W. CARSON, F.R.C.S.,

SENIOR SURGEON TO THE PRINCE OF WALES'S GENERAL HOSPITAL

EVERY surgeon recognises the difficulty of abdominal diagnosis, but we are all agreed that there are many more difficulties on the right side than on the left. When you think of the possibilities of error in left-sided abdominal diseases you see how few they are. It is true one may miss an early stomach cancer, one can mistake a spleen or a kidney for a colonic tumour, one may not realise how often a subacute appendicitis gives pain in the left iliac fossa or even the left hypochondrium. Diverticulitis may be difficult to diagnose and a left ureteric stone may require some study, but these are trifles compared with the right-sided pitfalls.

This is probably due to the protean activities of the appendix, and from the purely vicious, if unconscious, association of right-sided abdominal pain with disease of that organ. When we consider that until 30 years ago it was never suggested that in its quiescent state between attacks the appendix could give rise to symptoms, it is amazing how widespread is the belief that it is responsible for so many troubles. But in addition to the appendix *the right side of the abdomen has many traps for the unwary* and for the most skilful. Diseases of the gall-bladder are traditionally difficult to diagnose, and its close association with the duodenum, anatomically, perhaps, rather than pathologically, makes confusion easy between disorders of these neighbouring structures. Can we be sure of differentiating between those organs by the history, by the symptoms, by our abdominal examination, or by the exactitude of the ancillary methods of survey?

Two years ago or so my friend Dr. J. M. T. Finney, recently Professor of Surgery at Johns Hopkins University, Baltimore, visited at short notice my operation clinic at the Prince of Wales's General Hospital. I hoped to induce him to do his operation of pyloroplasty for duodenal ulcer, and did my best to obtain a case of duodenal ulcer off my list. The only case I could get in was a rather doubtful one, and when Dr. Finney and I went over the symptomatology and X-ray films, we were both unwilling to give a positive diagnosis of duodenal ulcer. He suggested that I should open the abdomen, and if it proved to be a case of duodenal ulcer he would do his operation. Exploration showed the case to be one of gall-stones, and Dr. Finney laughingly said: "It is delightful to come all these miles to see the same mistakes that I make myself!"

Duodenal Ulcer or Gall-stones?

In my experience, one is more apt to diagnose a cholecystitis as a duodenal ulcer than a duodenal ulcer as a cholecystitis. What are the points one relies on? Both those conditions tend to have periods of comparative freedom from symptoms. I am sure that the severe attacks of gall-stone colic are more severe and less amenable to treatment than the severe attacks of duodenal ulcer. I know that sometimes the duodenal ulcer patient will give a very lurid account of his sufferings, and I have seen patients in a bad attack obviously in great pain, but it does not compare with the true gall-stone colic which will cause vomiting, sweating, and collapse, and for which there is no remedy but morphia. But it is the quiescent period, or perhaps one should say in the semi-quiescent period, that real difficulty arises.

In making my preliminary diagnosis before I decide what ancillary investigations should be made, I rely on three points: (1) the history of the attacks; (2) the symptoms during the intervals (the duodenal case is generally quite well unless the appendix is also affected, while the gall-bladder often has flatulent dyspepsia and right shoulder aching); (3) the examination of the abdomen (comparative rigidity of the upper right rectus muscle in duodenal ulcer compared with the same condition of the upper oblique muscles), and Murphy's sign in gall-bladder. Murphy's test consists of an examination of the gall-bladder with the patient sitting up. The surgeon sits behind the patient and, placing his hands on the right and left hypochondria, directs the patient to relax his muscles and take a series of deep breaths. With each expiration the hands are pressed into the hypochondria, the palms of the hands being brought more and more horizontal—after three or four breaths the gall-bladder will be brought down during inspiration on to the fingers of the right hand, and if it is tender there will result a characteristic catch in the breathing. The test differentiates admirably between gall-bladder and kidney affections.

---

* Being a post-graduate lecture delivered before the Fellowship of Medicine on March 18th.

*One must not put too much reliance on physical con*figuration, although one is naturally inclined to consider the fair, fat-and-forty matron a more likely host of gall-stones than the thin fine-drawn male, nor must one expect too much help from the patient's likes and dislikes in food.

Special Methods of Investigation.

What of the ancillary methods? *Examination by X rays* has taken the foremost place in both cases. Both have their limitations. I think it will be agreed that radiographic examination after a barium meal does not give as high an average of successes in duodenal as in gastric ulcer. This is due to the fact that the great majority of duodenal ulcers are superficial—that is, there is no crater in which the barium can lodge; while in lesser curve ulcers, at any rate as the surgeon sees them, a crater or a bud is the rule. Craters are rare in duodenal ulcer unless the ulcer is on the posterior or inner surface, and these form quite a small proportion. *And then the shape of the duodenal cap may* be distorted by spasm due to many things, among them cholecystitis. I have under my care at the moment a medical man who has attacks characteristic of duodenal ulcer, with marked deformity of the cap, in whom symptoms occur only in association with phosphaturia and oxaluria. In only two respects does he differ from an ordinary duodenal ulcer; he vomits incessantly during the attack, and he has no hyperchlorhydria. The examination of the gall-bladder by X rays after the administration of the dye is still in its infancy, and has not yet given me the proportion of successful diagnosis which I *consider necessary if I am* to rely on it, nor is it yet decided whether the dye should be injected intravenously or given by the mouth in a cachet.

The Graham Cole test consists in the administration of 3 to 5 grammes of tetraiodophenolphthalein intravenously, in two doses of 35 to 50 grains in kerasol capsules by the mouth. The preliminary preparation of the patient is most important. The gall-bladder is examined radiographically *at varying intervals, beginning four hours* after the injection, or 12 hours after the oral administration, and examinations are repeated several times during the next 24 hours. A healthy gall-bladder *casts a shadow* which becomes gradually smaller and more concentrated, and finally disappears.

The other method is the chemical examination of the *stomach contents in duodenal ulcer*, and the microscopical and chemical examination of the duodenal contents in gall-bladder disease.

I am afraid we are all rather disappointed with the test-meal as a method of clinching the diagnosis. When the fractional test came in, we all hoped great things of it, and the curves certainly looked very instructive, but further experience shows such wide variations in the consecutive examinations that one has begun to lose faith in it. Perhaps the most helpful examination is that of the resting juice which may show variations, both chemical and microscopical, which may be very useful. *The examination of the duodenal* contents by Vincent Lyon's method has never really caught hold of English investigators. I was in Philadelphia last December, and had the great pleasure of seeing my friend, Dr. Lyon, at work. *His method consists in the introduction* directly into the duodenum by means of the Rehfuss tube of 50 c.cm. of a 25 per cent. solution of magnesium sulphate. This gives rise to a rapid discharge of bile, which is then aspirated through the tube. Lyon differentiates between the A bile, first to come, from the common bile-duct, the B bile, second to come, from the gall-bladder, and the C bile from the hepatic ducts, which comes last. In some patients, 15 c.cm. of melted butter, or 30 c.cm. of cream and egg yolk give equally good results.

He showed me some strange things, and there is no doubt that quite a deal of information is forthcoming from this method of investigation both in gall-bladder disease and duodenal ulcer, and there is no doubt it will make its way.

At one time I thought I proved to my own satisfaction *that Bacillus coli cystitis was often associated with gall*-stones, but it is only a chance happening, I believe. Also, we hoped that we might find an excess of cholesterol in the blood, but this has also come to nothing.

Symptoms arising in the Urinary Tract.

My reference to oxaluria may excuse a digression to refer to the very baffling symptoms that this condition can give rise to. My first experience was some 25 years ago, when I dared to disagree with that very eminent surgeon, Mr. C. J. Bond, of Leicester, over the diagnosis in the case of a well-known master of hounds. My diagnosis, which was of appendicitis, carried conviction against Mr. Bond's diagnosis of a minute ureteric stone, and I operated, and have still on my desk an ink-stand given to me by my grateful patient. I sent him away on a sea voyage, and while he was in the West Indies he had a similar attack to the old ones and passed a minute oxalate stone. He sent it to me with a cheery letter. The ink-stand is a *constant check upon any desire I may have to consider* myself infallible.

The last case occurred some two years ago, when I was called upon to see a man who had apparently a severe attack of intestinal obstruction. He was collapsed, vomiting, distended, and all the rest of it. I explored him and found nothing except generalised intestinal distension. I advised the doctor to keep a sharp look-out for the passage of a urinary stone. For three or four days his life seemed to hang in the balance, but he recovered, and 14 days after his seizure he passed an oxalate stone and has remained well. *And that brings me on to the subject of the differen*tiation between the appendix and some renal lesions.

The acute infections are more easy than the chronic recurring attacks. I do not think one ought to mistake a perinephric abscess of hæmatogenous origin for a retrocæcal appendix abscess. The former is never so acute, and rarely leads to an abdominal mass. But to distinguish between a retrocæcal appendicitis and acute ascending pyelitis of pregnancy may be very difficult, especially if the kidney is not functioning, so that pus does not appear in the urine. The most valuable signs of pyelitis are: (1) *acute tenderness in the costovertebral angle*, (2) an initial rigor, and (3) a temperature perhaps as high as 101° F., but certainly higher than is usual in acute appendicitis. Dietl's crises (an intermittent hydronephrosis due to kinking of the upper ureter) may lead to an error, but there is rarely any need for hurry in those cases, and a pyelogram will settle the diagnosis without difficulty.

Appendicitis.

There is the old warning of the danger of mistaking a perforated duodenal ulcer for an acute appendicitis on the grounds that the duodenal contents tend to gravitate to the right iliac fossa and give rise to signs in the appendix area. I am sorry I cannot subscribe to this opinion of difficulty. Even in the absence of a previous history of duodenal indigestion, the *onset*, the *general character* of the abdominal rigidity, and especially the condition of the patient, all tend to make the differentiation easy, and I do not think the mistake should be made, nor is it, I believe, made very often. But I will tell you of an *exercise which* will help you. In any case where I suspect an acute appendicitis, I always set myself and my house surgeon the task of stating the exact position and appearance of the appendix before I operate. As experience accumulates one gets nearer and nearer to the truth, and I have found it particularly valuable in diagnosing the acute retrocæcal appendix which is always the *most difficult*.

Among the more chronic lesions, the differentiation between appendicitis and ureteric stone may be very difficult if for any reason the stone cannot be localised with X rays. *One has then to rely upon the possible occurrence* of urinary symptoms, the presence of abnormalities in the urine, and a cystoscopic examination. That many mistakes are made is evidenced by the number of cases of kidney and ureteric stone we see in which the appendix has already been *removed* without relief. They come to a high proportion of the cases. The only safeguard is that which results from our hospital system where every patient passes through many hands before the diagnosis is definitely settled.

The Distinction of Pain and Tenderness.

Perhaps the greatest difficulty of all, however, is to make a correct diagnosis in the common case of a patient complaining of right iliac fossa pain. Here I would like to draw a distinction between pain and tenderness. Conditions giving rise to *tenderness* are much more easily diagnosed than those giving rise to pain, for pain is purely subjective and varies in significance according to the sufferer's make-up.

Three girls consult you, and each give a story of vague diffuse abdominal pain confined to the right side. The first is apparently in excellent health, you can make nothing out in examination, but you get a history that she has been *vigorously engaged in some sport such as lacrosse or basket*-ball, or lawn-tennis, all designed to put a strain on the right lower abdomen. You suspect a strained external oblique, or even a commencing hernia. The second is equally healthy. She tells you that *last October she had* a rather severe attack of abdominal pain, perhaps with vomiting, that she had to lie up for a week or so, and that she still gets occasional discomfort in the right iliac fossa. You suspect an attack of appendicitis which has *not entirely* subsided. The third is perhaps not quite so healthy or active, and on cross-examination she admits that the pain has been there for a long time, that it gets worse as the day goes on, but is relieved by lying down, *that she is tired* at night, and constipated. You suspect enteroptosis, and find confirmation on examining her general physique and noting the skeletal changes, the loss of weight, the muddy complexion, the circulatory abnormalities which characterise this most common and distressing malady.

It was Dickens, I think, who drew a word-picture of the woman who is fated to be killed by her husband, and this picture is a perfect reproduction of the enteroptotic woman.

Enteroptosis.

I am often asked whether X rays are a help in the diagnosis of appendicitis or enteroptosis. The answer is, that they will help but their value must not be exaggerated. It used to be said that a pathological appendix was evidenced (1) if the barium entered the appendix and remained there for a long time, thus showing that the peristaltic power of the appendix was diminished by fibrosis of the wall, or (2) if the barium did not enter at all, thus showing obstruction of the lumen. But now all are agreed, I believe, that no radiological opinions are to be expressed unless the appendix is visualised. If it is, some opinion can be passed as to whether it is tender—a rather doubtful point—or whether it is abnormally fixed. Enteroptosis, or at any rate a pathological hypermobility of the colon, is also very difficult to estimate by X rays. Everyone of my age was taught that the hepatic flexure was up under the rib, and the caput cæci above the level of the pelvic brim. We know now that in the erect position in health the hepatic flexure is rarely much above the intercristal line, and the caput cæci is quite often in the true pelvis. The same is true of the transverse colon, which, instead of passing obliquely across the umbilical region up to the splenic flexion, much more often sags in the middle almost into the pelvis. What, then, are the radiographers' evidences of a pathological enteroptosis? They may be summed up as evidence of abnormal fixation and delayed function. If the cæcum or transverse colon are abnormally placed and fixed, that is pathological; and if the barium remains too long in the lower ileum or cæcum, this is pathological.

There is one justification for an aphorism which I permitted myself when talking about the operative treatment of intestinal stasis, that it is more surgical to free abnormally fixed organs than to fix abnormally free organs.

Tuberculous Lymphadenitis.

Symptoms which one may confuse with those of the chronic appendix are caused by tuberculous mesenteric glands. These are generally seen in children, though they may occur at any age. They give rise to a characteristic train of symptoms—of which colicky pain is the most important—which are now well recognised since I first brought them before the profession in 1918. When I was in Toronto, in December, I was told that so thorough was the control of the milk-supply that these cases hardly ever occurred. However, they are still frequent, though I think less frequent than they were in London, their incidence having fallen in common with all forms of surgical tuberculosis. A good deal of discussion has centred round the question of whether chronic appendicitis does occur and cause symptoms in children. I have no doubt of it myself, and I am not alone in thinking that some, at least, of the intestinal indigestion so common in children is due to lesions of the appendix. Generally, however, in children, especially in little children, localisation is not very exact, and the patients seem to complain of pain in the umbilical region rather than in the right iliac fossa. Of all forms of interval appendicitis in children, the mucocele gives rise to symptoms most closely resembling those of tuberculous mesenteric glands.

Finally, I might perhaps suggest that we should all make fewer mistakes in diagnosis in right-sided abdominal lesions if we were not obsessed by the ever-present shadow of the appendix.

LOCAL AUTHORITIES AND MATERNAL DEATHS.

To facilitate inquiry into the causes of mortality in childbirth, local authorities having charge of maternity and child welfare may wish to obtain particulars of maternal deaths occurring in their areas, and the Ministry of Health has been in consultation with the Registrar-General as to the best method of procedure. Reports received by the Registrar-General indicate that some difficulties are being experienced both by local authorities and by registrars of births and deaths in establishing satisfactory plans for the provision of early information respecting the occurrence of maternal deaths. It is understood that in some cases registrars of births and deaths are being asked to identify "maternal deaths" in the sense of deaths due to puerperal sepsis and other diseases of pregnancy and parturition. This general grouping comprises over 150 individual causes of death, as enumerated in the Registrar-General's Manual, and the burden of watching for the appearance upon medical certificates of any of these separate causes is one which, in the opinion of the Registrar-General, registrars cannot properly be expected to undertake. Moreover, even if it were possible for this task to be performed without prejudice to the performance of the registrar's normal duties, local authorities would not thereby secure the complete notification of all "maternal deaths," since certifying practitioners often employ an alternative terminology for many of these causes which could not be identified without medical knowledge.

On these grounds the Registrar-General is disposed to deprecate any such arrangement between a local authority and a registrar of births and deaths. It appears to him that the final identification of deaths as falling within the definition of "maternal mortality" is one which can only be made by persons with medical knowledge, and that this selection must necessarily take place after the receipt of the material by the local authority. Where the local authority already obtains complete returns of all deaths under the provisions of Section 28 of the Births and Deaths Registration Act, 1874, or is now prepared to obtain complete returns for the service of its public health administration in regard to both maternal mortality and other matters, no further question will arise. But where the local authority desires information for the purpose of maternal mortality only, and has no other object in view which would justify the provision of complete returns, this purpose would be adequately served by arrangements for the notifications of deaths of females between, say, 15 and 45 years of age.

This section of the death registers would be sufficient to enable the proper selection of maternal deaths to be made therefrom, and the Registrar-General is not at present aware of any other practicable criterion which would meet the purposes in view.

ULTRA-VIOLET APPARATUS.

THE sixth edition of the "Arnold" ultra-violet and other apparatus issued by Messrs. John Bell and Croyden is a useful publication. It contains illustrations, descriptions, and price-lists of a considerable variety of sources of ultra-violet, luminous, and infra-red radiation, together with a detailed account of accessory gear used with these forms of therapy. The protective goggles used in all light clinics should be tested for their transparency to ultra-violet radiation, for many a black glass lets these rays through. The particular goggles illustrated here are, we believe, safe varieties, and those shown on p. 30 are inexpensive and very suitable for hospital work. Mention is made of a useful kind of garment which can be worn during exposure of the body to ultra-violet. This material consists of a mixture of pure wool and artificial silk, which is said to pass approximately 50 per cent. of the ultra-violet; the openness of the mesh may be mainly responsible for this transmission.

UTERINE FIXATION BY TRANSPLANTED FASCIA.

THE operative treatment of retroflexion of the uterus entails certain disadvantages. The Alexander-Adams method, that of shortening the round ligament, avoids adhesions, but the ligament is apt to stretch in women who have to carry heavy weights. Dr. N. A. Podkaminisky, of the Ukraine National Institute of Industrial Pathology and Hygiene, Charkov, suggests an operation which will fulfil the two requirements of permanence and the avoidance of adhesions without altering the length of the round ligament. He proposes to transplant two strips from the fascia lata into the abdominal cavity and attach them to the ends of the round ligament, suturing them along its whole extent. By this means there should be no displacement of the organs in a small pelvis. Observations from the use of strips of fascia for other purposes show that they readily unite with their new neighbours and lose no elasticity or vascular function; they receive, in fact, an additional supply of blood through the new vessels of the scar-tissue. The author is satisfied with the results of the operation, which are to be communicated later.

ROBB'S DIETETIC BISCUITS.

WE have received from Messrs. Robb and Co., Ltd., Nursery Biscuit Factory, Atkins-road, Clapham Park, London, specimens of their well-known productions, including oatmeal biscuits, wheatmeal biscuits, water biscuits, for general use with butter, cheese, and fruit; Bath Oliver biscuits, recommended for indigestion and table use; ginger nuts, rusks of various kinds, and dietetic biscuits, together with their food biscuits for infants. The productions of this firm, which are manufactured with due regard to the requirements of infants and invalids, are palatable and easily digestible, and find a place in many households. The firm will send trial samples to medical men or nurses on application.

Dosage of Isopral and Hedonal.—Dr. A. E. Beryl Harding writes that the dose of isopral and hedonal recommended by Lambert (THE LANCET, March 2nd, 1929, p. 433, col. 1), as a preliminary injection in the anæsthetisation of cats, should have been given as *0·15* (not 1·15) c.cm. per kg.

Lumleian Lectures

ENTITLED

A MEDICAL REVIEW OF THE SURGERY OF THE CHEST.

Delivered before the Royal College of Physicians of London.

By R. A. YOUNG, C.B.E., M.D., B.Sc. Lond.,

FELLOW OF THE COLLEGE; SENIOR PHYSICIAN TO THE MIDDLESEX HOSPITAL; PHYSICIAN TO THE BROMPTON HOSPITAL FOR CONSUMPTION AND DISEASES OF THE CHEST.

LECTURE III.*—SURGERY IN PLEURAL AND MEDIASTINAL CONDITIONS.

(Delivered on March 26th, 1929.)

IT seems probable that the pleura was one of the first parts of the body upon which surgery was successfully practised, while the mediastinum, owing to the difficulty of access and the complexity and importance of the structures contained in it, is one of the last to afford a safe field to the surgeon. Some of the most difficult problems and most vexed questions in thoracic medicine and surgery are afforded by disease or damage in these regions.

SURGERY IN ABNORMAL CONDITIONS OF THE PLEURA.

The first of these which demands consideration is that of empyema.

Acute Empyema.

The treatment of this condition has until recently been far from satisfactory, yet it is strange to find that the modern principles were clearly stated by Hippocrates. His teaching as abstracted by Stephen Paget [1] was as follows:—

> "Having carefully washed your patient with warm water, you must seat him on a firm chair, and then, while your assistant steadies his hands, you must gently shake him by the shoulders, in the hope of obtaining a splashing sound in the affected side of the chest. Operation should not be performed before the fifteenth day after the beginning of his illness. An incision must be made through the skin, where the pain and swelling are most evident, and then the pleura must be opened, either by trephining the rib, or with a sharp instrument, or with the actual cautery. When a sufficient quantity of pus has been let out (and those who suffer from empyema or dropsy of the chest are sure to die if you *rapidly* evacuate the pus or the water), you must keep the wound open with a strip of linen cloth, secured with a thread. *This strip must be removed daily, that the* remainder of the pus may run out. On the tenth day after the operation you must irrigate the cavity with warm wine and oil, for the purpose of cleansing the surface of the lung; these irrigations must be made twice a day. Finally, when the discharge has become thin and serous, you must keep a small rod of metal in the wound, using a smaller size from time, to time till the whole wound has healed."

It is worthy of note that Hippocrates advises cleanliness with no drainage till the fifteenth day, that he used irrigation, and that he recognised the necessity of keeping the wound open till the infection had subsided.

From the time of Hippocrates until recently the treatment of empyema forms a lamentable chapter in the history of medicine and surgery. The Hippocratic rules were followed till the fifth or sixth century, and afterwards were discarded or forgotten, although the cautery and even caustics were sometimes used by the Arabians. Ambroise Paré came nearer to the methods of Hippocrates, for he employed intercostal incision and even resected ribs. In spite of this, repeated aspiration replaced this operation. One surgeon made 74 punctures in nine months in a child of 11 years, obtaining in all 30 pints of pus, and in 1872 a case was published by Bouchut in which the chest was punctured 122 times in 11 months. Till Lister's discoveries there were comparatively few successes from incision, and Dupuytren, when he himself suffered from empyema, refused operation, which is not surprising when his own record was only four recoveries out of 50 cases. Velpeau had no recoveries out of 12 cases, and Sir Astley Cooper said that he could never get a single cure.

One of the most notable landmarks in the history of the treatment of this condition is the report of the Empyema Commission [2] carried out in America at the instance of the United States Army authorities. It was initiated because of the heavy mortality observed in the military camps of that country in the winter of 1917–18, following an epidemic of hæmolytic streptococcus infections of the respiratory tract. The average mortality of the empyema cases before the Commission started its work was 30·2 per cent., and in some camps it was as high as 84 per cent. As a result of the work of the Commission, in the cases treated by them it fell to 4·3 per cent., and they came to the conclusion that death should not occur in cases of empyema, other than tuberculous empyema, unless it were complicated by such conditions as lung abscess and suppurative pericarditis. The occasional occurrence of cerebral abscess can also neither be foreseen nor prevented.

Graham,[3] who was a member of the Commission, and whose admirable and philosophic Gross Prize Essay should be widely studied, points out that there is a marked difference between empyema due to the streptococcus and that due to the pneumococcus, both in pathological development and course. He further suggests that the high mortality in the streptococcal cases is the result of applying to their treatment the principles commonly and correctly applied to pneumococcal cases. There are two fundamental differences between them. In pneumococcal cases the effusion does not generally develop into pus until after the pneumonia has subsided, such cases being called meta-pneumonic. In streptococcal cases the effusion often develops early and is copious and rapidly formed, being thus syn-pneumonic and adding to the dyspnœa and cyanosis. The other difference between the two types is that in pneumococcal cases the infected part of the pleura is soon walled off from the general pleural space by adhesions, while in the streptococcal cases the condition is at first one of fluid free in the pleural space, and generally of thin, sero-purulent character, yet loaded with streptococci. At this stage the condition would be more accurately described as a "pyothorax," as urged by Tudor Edwards.[4] Any attempt to drain the pleura must produce a more or less complete open pyopneumothorax with all its dangers, which are greatly increased, as Graham points out, by the diminished vital capacity, due to the associated lung condition—viz., broncho-pneumonia or collapse, and to the free unfixed mediastinum. On the other hand, if aspiration only is carried out in streptococcal cases at first, relief is given to urgent symptoms, and time is allowed for adhesions to form and thus to localise the fluid into a true empyema. The question naturally arises as to how this event can be recognised. Radiographic investigation may help and should be carried out where possible, but in general a useful and safe criterion is the appearance on aspiration of frank pus instead of the thin sero-purulent fluid. The difference is somewhat reminiscent of the old distinction between "thin, sanious" and "laudable" pus. It is significant in this connexion that Cameron and Osman [5] found that syn-pneumonic empyema in infants was a very fatal condition if early open operation were carried out, and that the meta-pneumonic cases usually recovered.

The Empyema Commission found that, as a rule, the interval between the onset of the streptococcal pneumonia and the development of frank pus was from two to three weeks. On an average four aspirations were carried out during that time. The most important outcome of the Commission's report is that empyema is *not* to be regarded as an acute surgical emergency requiring operation as soon as it seriously diminishes the vital capacity, as has been shown by Graham.

---

* Lectures I. and II. appeared in THE LANCET of March 23rd and April 6th respectively.

It was shown by Delorme,[12] in 1893, by some experiments on animals, that even after long compression and collapse by thick organised exudate on the visceral pleura, the lung could expand if this constricting exudate were removed. Quite independently, G. R. Fowler,[13] in October of the same year, carried out an operation devised to liberate the lung. The operation is therefore called the Fowler-Delorme operation of decortication. In many instances this proves to be easier than might be expected. If the plane between the pleura and the adherent membrane can be reached, it is often possible to strip off the latter, when the lung readily expands, especially if the operation is carried out under intratracheal anæsthesia. It is not necessary to remove the membrane from the parietal pleura except at its reflexion on to the visceral layer.

If removal prove to be impracticable, the ingenious manœuvre of discission, suggested by Ransohoff[14] may serve to allow the compressed lung to expand. He criss-crosses or gridirons the thickened adherent exudate down to the level of the pleura by incisions at right angles to one another at a distance of one-quarter of an inch. On gently increasing the intrapulmonary pressure, the incisions widen and considerable expansion of the lung may result, but rarely of sufficient degree to enable the empyema cavity to close.

An operation has been devised and carried out by Colonel W. L. Keller[15] which attempts to achieve both objects of falling in of the chest wall and decortication. He makes a large incision, carries out extensive rib resections, removes the parietal pleura in so far as may be necessary, and carries out a chemical decortication by means of gentian violet, after which the cavity is regularly irrigated with Dakin's solution.

All these procedures involve serious operative manipulation in patients already debilitated by long discharges and with diminished vital capacity, and are not to be undertaken lightly.

A high mortality in empyema cases and a high percentage of chronic empyemata in any series should lead those concerned both from the medical and surgical sides to consider whether there may not be some defect in diagnosis or in treatment.

Tuberculous Empyema.

Pus developing in the pleural cavity in association with pulmonary and pleural tuberculosis is a most troublesome condition, and may be a most serious complication. The term "tuberculous empyema" is unfortunately somewhat loosely applied to several conditions, different in origin, nature, and severity, viz.: (1) A serous, tuberculous effusion which becomes chronic may in course of time become more cellular, especially after tapping, and eventually purulent. This is a tuberculous pyothorax, and if localised could strictly be called a tuberculous empyema. (2) It is well known that in artificial pneumothorax treatment effusion develops in about 50 per cent. of the cases, and that in a fair proportion of these it eventually becomes purulent. This condition is really one of tuberculous pyopneumothorax. A similar condition may develop in cases of spontaneous pneumothorax caused by tuberculous lesions. In such cases the pus may cause little inconvenience, and may only require repeated aspiration or replacement. (3) Cases of pyopneumothorax due to lung rupture or lung puncture, in which secondary infection occurs. This is a most grave condition and may arise in at least four different ways—viz., (1) from lung puncture, either at the initial induction of a therapeutic pneumothorax or, very rarely, from a diagnostic puncture; (2) from rupture of adhesions involving the lung, especially if positive pressures have been used; (3) spontaneous rupture of a subpleural focus of caseation or of a cavity; (4) rupture of a pyopneumothorax through the visceral pleura into a bronchus. In all of these conditions, but especially in the last two, there is the added risk of secondary septic infection of the pleura. The outlook for these patients, apart from active treatment, is extremely grave. On the other hand, Hutchison and Blair[16] suggest that lung rupture in the course of pneumothorax treatment may be commoner than is generally supposed. They observed this complication seven times in the treatment of 120 cases. They describe a typical temperature chart with a sudden rise and a gradual staircase fall in which the previous daily variation of temperature is roughly preserved, with physical signs indicating sudden displacement of the mediastinum and with a change in the intrapleural pressures. By contrast with instances of this type, cases of rupture with secondary septic infection of the pleura may be fulminatingly acute and associated with great shock. It is obvious, therefore, that cases of tuberculous disease in which purulent effusions occur into the pleura, require careful investigation to establish their nature.

My colleague, Dr. L. S. T. Burrell, has been kind enough to give me some very striking statistics of his cases and details of the methods of treatment which he has found most helpful. He found that of his first 309 cases of artificial pneumothorax treatment for pulmonary tuberculosis 181 had no definite effusion—i.e., at most a small amount. Of these 181, 57 were dead in 1926 (31·5 per cent.). Effusion of definite amount occurred in 128, of which 47 (36·7 per cent.) were dead in 1926. In these 128 cases the fluid was clear in 92, of whom 27 (29·4 per cent.) were dead in 1926. In the remaining 36 cases the fluid was pus. Of these patients 20 had died by 1926 (55·6 per cent.). This notably high mortality in cases in which purulent effusion occurs, as compared with those in which the effusion is serous, decided Dr. Burrell[17] to aspirate all cases in which pus occurs, and to try to get the lung to expand. He writes:—

> "If the pus is too thick to aspirate, I introduce 20 c.cm. of Gauvain's modifying fluid (guaiacol g. 2, creosote g. 2, iodoform g. 5, ether g. 10, sterile olive oil 100 c.cm.) and leave this in for 24 hours, by which time the fluid can generally be aspirated easily. I then wash out the pleural cavity with 1 in 5000 methylene-blue solution until it is completely clear, and introduce enough oxygen to allow easy aspiration. but not enough to raise the pressure beyond –6 cm. of water. I watch carefully with the X ray, and if the lung begins to re-expand I encourage this by further aspirations and wash-outs, but if there is no re-expansion I advise thoracoplasty. I carry out the same procedure for spontaneous pneumothorax when once pus forms."

Dr. Burrell's experience of dealing with these cases by this method is encouraging. There is one point which cannot be too strongly emphasised, and that is that purulent effusions in tuberculous disease should never be treated by open drainage, since this can only lead to pneumothorax with permanent external opening. Where this has unfortunately been done, the only hope is in washing out the cavity and eventually carrying out a thoracoplasty in stages if the patient's condition will permit.

Oleothorax.

There is, however, another method of treating these cases of tuberculous effusion which is worthy of note, and that is by introducing oil into the pleural cavity. This was first employed by Weill in 1918 for cases of pyothorax. He used only small quantities of oil, to which oil of gomenol had been added. Archibald and de Carle Woodcock had also tried experiments with liquid paraffin. Bernou, in 1922,[18] used much larger quantities, and the name of "oleothorax" is now applied to this form of treatment. Sterile olive oil or liquid paraffin is used, and oil of gomenol is added in strengths of 5 to 20 per cent. From 400–600 c.cm. are injected, air, fluid, or pus being withdrawn at the same time as the oil is introduced. Burnard[19] introduces as much as 1000 c.cm. These large quantities should only be injected where the pleura has been infected, or where it has been distended with fluid or gas. An interesting study of this subject has been published in this country by Chandler and Roodhouse Gloyne.[20] They give details of the method and a summary of the conditions in which it may be useful. These include cases of chronic effusion and of tuberculous pyothorax, and especially cases where rupture of the lung has occurred. Oleothorax is believed to have an antiseptic action if gomenol is employed, and it may help to secure healing of the rupture. If it fails, then thoracoplasty should be considered.

I may here add, in parentheses, that oleothorax has been recommended for other purposes, viz.: (1) To obviate frequent refills in artificial pneumothorax treatment, where they are not easy to obtain or are undesirable. (2) To limit or prevent adhesions. In this case, if the condition is one of "virgin" pleura—i.e., where air, fluid, or pus are not present—only small quantities should be introduced at first. (3) To delay the progress of obliterative pneumothorax, which often prevents the continuance of artificial pneumothorax threatment.

Dr. R. C. Wingfield has used it at Frimley in three cases with encouraging results. It is to be noted that there is often a definite febrile reaction after the injections of oil.

The method of oleothorax is still on trial, but it promises to be of use in selected cases. At present, however, its field of usefulness is restricted.

Hæmothorax and Wounds of the Pleura and Lungs.

Hæmothorax is most frequently the result of injury or wounds of the pleura and lung. It may, however, occur in other conditions, such as injury or disease of the mediastinum, notably from rupture of an aneurysm or from erosion of vessels by new growth. In cases due to causes other than injury, the condition is usually serious and often rapidly fatal.

The general principles of treatment of hæmothorax after injury have been established by the large war experience of this condition. The report in the "Official History of the War" on Wounds of the Chest, by Prof. T. R. Elliott,[21] to which I have already referred, should become a classic. It gives a clear statement of the general principles upon which chest wounds should be treated, and affords a striking example of the advantages of friendly coöperation by physicians and surgeons.

Prof. Elliott states that prompt surgical treatment can diminish considerably the number of early deaths, and can lessen the period of invalidism by preventing the development of empyema. Thoracotomy and excision of the wound proved to be of the greatest service. He points out that "during the first three weeks all patients must be carefully watched for possible development of intrapleural sepsis, and after that period they need steady attention in order to ensure good expansion of lungs that may have been collapsed beneath a hæmothorax or an empyema." It was found, as was well known previously, that operation was unnecessary in cases of uninfected hæmothorax of small size, such cases nearly always recovering without interference. With large effusions causing any dyspnœa or distress, early aspiration is practicable and advisable, the theoretical objection that the hæmorrhage might recur being unfounded, since clotting of the effused blood takes place with little delay. Early operation is indicated in cases of large simple hæmothorax in a state of massive clot.

In acute infected hæmothorax, infection may spread virulently through the hæmothorax within 24 hours of the wound, while sometimes it may be present and not afford clinical evidence for days. At the earliest evidence of sepsis, whether rise of temperature, development of other general symptoms from examination of the fluid withdrawn, operation, and drainage as soon as possible are recommended. In view, however, of the experience of the Empyema Commission in septic pleural conditions, it would be well in such cases to aspirate repeatedly or to drain by a closed method until frank pus is obtained.

Another condition in which primary and early operation is advised is in abdomino-thoracic wounds with injury of the diaphragm, especially on the left side.

Tumours of the Pleura.

These may be either simple, such as lipoma, fibroma, and perhaps chondroma, or malignant, of which the chief varieties are endothelioma and sarcoma of various kinds.

If a simple tumour is of sufficient size to give rise to symptoms, it should be removed. Malignant tumours of the pleura are rarely diagnosed at a stage when operation is practicable. Cases of endothelioma sometimes commence in a localised form, and if diagnosed should be submitted to the surgeon. The early development of fluid complicates the problem of diagnosis, but we may hope that the earlier use of X rays and possibly diagnostic pneumothorax and thoracoscopy may render some of these cases amenable to early operation, with a chance of success

SURGERY IN MEDIASTINAL CONDITIONS.

There is at present only a restricted field for surgery in the mediastinum. With characteristic ingenuity, surgeons have worked out methods of access to the various divisions of the mediastinum. The anatomical difficulties have been overcome. The real bar to any extensive surgical operation is the loose areolar tissue which intervenes between the important organs situated in the mediastinum. Once infection reaches this tissue, it is difficult to limit its spread.

The superior and anterior mediastina are readily exposed by splitting the sternum. This operation of anterior mediastinotomy was first described by Milton, of Cairo,[22] in 1897, and has recently been extensively employed. The posterior mediastinum can be reached by an operation in which ribs are divided and shingled upon one another after certain sections have been removed. This is Lilienthal's [23] modification of the older operations of Bryant and Enderlen. It is known as posterior mediastinotomy.

The mediastinum can also be reached by a transpleural route after thoracotomy, and this mode of entry is used for certain tumours. The chief conditions in which the physician may require the surgeon's aid are: (1) suppurative mediastinitis, (2) mediastinal tumours and cysts, (3) mediastinal emphysema.

Suppurative Mediastinitis.

This may be either acute or chronic. The acute cases may be traumatic from penetrating wounds or crushing injuries. Perforation and injury of the œsophagus, and ulceration or injuries of the trachea and bronchi from inhaled foreign body, disease of the sternum, vertebræ, or ribs, may all lead to suppuration in the mediastinum. Suppurative conditions of the lungs, pericardium, pleura, or peritoneum may extend into the mediastinum. A suppurating hydatid or dermoid cyst may rupture into it. An empyema near the mediastinum may give rise to the "mediastinal syndrome," as pointed out by Dieulafoy, although the condition is really extra-mediastinal.

The suppurative process is very liable to spread widely, in which case the condition is almost hopeless. On the other hand, if it become localised, it can be reached by the surgeon and drained.

Chronic mediastinal abscesses are usually the result of tuberculous conditions of the mediastinal glands or of the bony walls of the mediastinum. They are usually to be treated like other "cold" abscesses, by aspiration and injections. If due to other causes, drainage is to be effected if practicable.

Mediastinal Tumours and Cysts.

It is in this connexion that the most useful developments of surgery have occurred. Encapsulated tumours and cysts can as a rule be removed readily and without undue risk.

Among the tumours met with are mediastinal goitre, lipoma, chondroma, myoma, fibroma, osteochondroma, and ganglion-neuroma. The cystic

CASE 4. *Complete flaccid paralysis with wrist-drop of the right arm, following a superficial petrol burn; 18 months' duration; no improvement after months of massage and electricity.*—Lorry driver, aged 26, sustained a superficial but extensive petrol burn of the right arm on Jan. 19th, 1927. Healing was delayed but ultimately occurred and left no scar. Owing to the delay in healing he forgot how to use the arm, and complete flaccid paralysis occurred for which he was treated by massage, electricity, and other physical treatments for many months. It was not easy to persuade him that he was wrong in thinking "that petrol burns in and destroys the tendons," and I failed to cure him by psychotherapy after three sessions, each lasting one hour. He returned to treatment by massage and electrical stimulation.

It must be clear that treatment by argument and persuasion is difficult under these conditions. Nevertheless, most doctors are aware of the failure of treatment by massage and electricity, and of the necessity for psychological treatment. It is a pity, therefore, that so little effort is made to apply simple psychological principles, as I believe most of these hysterical disorders can be prevented by the man's own medical attendant. When litigation is at an end and the claim has been settled, physical measures are more likely to be attended by some success, for the man's anxiety has been relieved and he is keen to become a wage-earner again. There can be little doubt that many of these men believe they will be better off if they can secure a lump sum in settlement of their claim. Visions of a small personal business and the joy of being their own master arise in their minds. Too often, unfortunately, does the man invest this money in some business of which he has neither experience nor business capability, and in a short time he is worse off than before. In several cases I have found that the wife or daughter is given charge of the business while the applicant idles his time. These men find it very difficult to secure other employment, as most employers look askance at the man who has already had an accident and been paid a lump sum in compensation.

The following case shows how a man after the claim was settled speedily lost his symptoms and succeeded in spending the money.

CASE 5. *Hysterical gait following compound fracture of both bones of the leg, the result of a motor accident. Complete recovery on settlement of his claim.*—A motor-driver, aged 30, when driving a motor-cycle combination on Sept. 4th, 1926, collided with a motor lorry and sustained a compound fracture of both bones of the right leg. He was in splints and extension for 13 weeks, and was subsequently treated by massage three times a week until April, 1927. In July he was put in charge of a petrol-filling station, as he said he could not apply sufficient pressure with the foot to use the brake of a light car. Despite good bony union and alignment and full movement in the joints, he continued to walk with an awkward gait. On my advice compensation was stopped and the case was heard in court. The claim was settled for a lump sum. Within a week he had bought a new motor-cycle combination and was touring the countryside with vigour. His own doctor, who gave evidence on his behalf, subsequently confessed that my opinion as regards his capability to drive a light car was the correct one. Incidentally, the man was dismissed his employment because of slackness of trade.

The following cases are illustrative of a few hysterical conditions that have been examined by me recently, none of whom show any improvement despite prolonged treatment by ordinary physical measures.

CASE 6. *Hysterical contracture of the fingers after falling; eight months' duration.*—Labourer, aged 30, fell on some planks on Oct. 15th, 1927, bruising his right fingers. He continued at work for a few days despite pain and swelling, and then consulted his doctor. An X ray photograph showed no broken bones or damage in the joints, but despite all local treatment the fingers remained flexed and could not be extended. He did not return to work until January, 1928, but gave up because of pain and tried again in February. Examination showed that the right hand was clammy with the fingers semi-flexed. He could not straighten the fingers voluntarily, and attempts to do so were resisted by active spasm of the flexor muscles. The condition was recognised by his doctor as being "functional," but no attempt was made to teach him relaxation.

CASE 7. *Hysterical wry-neck after a blow on the head; 14 months' duration.*—A collier, aged 40, received a blow on the head from a tub coming off the rails on March 18th, 1927. He was stunned for a few minutes but was able to resume work and finish the shift. His doctor ordered liniment. On March 24th, 1927, he returned to work but gave up because of pain and stiffness in the neck. He then commenced treatment by massage and electricity, which was continued regularly for a period of 13 months but without benefit. X rays showed no fracture and eventually a neck support was ordered which, however, the man refused to wear.

On examination the head was found to be bent forcibly towards the left shoulder, and he was unable to lift it by his own efforts. Attempts to overcome the spasm were resisted by clonic movements of the head, but in a few minutes the head was erect and remained so without support for a few seconds, thereafter resuming the shoulder position. There is no doubt that this is a case of hysterical wry-neck, the position adopted being the one in which he got most relief at the time of his injury. It has been perpetuated long after the necessity for it has passed away. The man's idea of incurability was fostered by the failure of prolonged massage, &c., and yet after a few minutes' gentle persuasion the head was erect and no doubt further re-education would have enabled the man to keep it so.

CASE 8. *Hysterical tremor and slight stammer after compression between two motor-buses; similar condition in 1915 from shell-shock.*—A bus conductor, aged 40, got momentarily squeezed between the back of his stationary bus and the oncoming radiator of another. He was taken to the Royal Infirmary but discharged the same night, as no injuries were discovered. Next day he was trembling all over and had difficulty in speaking. Examination failed to reveal any organic nervous disease, and the tremor was a typical hysterical coarse tremor. A similar condition had been present in 1915 as the result of shell-shock, and he was cured of this in a London hospital on psychological lines with complete recovery.

The variety of symptoms which can occur is legion. The commonest are paralysis of a limb—either flaccid or spastic, contractures, tremors, stammering, awkward gait, and bent backs. Less common are defects of vision and hearing. The symptom most difficult to decide upon is probably pain, but this symptom is just as likely as any other to be perpetuated by suggestion in the man's mind long after the original cause of the pain has been removed. For example, very few surgeons are troubled by complaints of pain in the scar following the radical cure of hernia in private cases, but I have rarely come across a compensation case who did not complain of pain in the scar, despite the fact that otherwise the operation was a success. Too often this pain is encouraged by a medical opinion that a nerve is involved in the scar, and I have even known a second operation performed to relieve this nerve-ending, but without the promised relief. The psychic element is too often overlooked.

In spastic conditions of muscle pain probably does exist to some extent, but this is a physiological result of a constant state of cramp. Immediate relief comes when the man learns to relax the spasm, but this relaxation requires a mental effort; treatment by baths, massage, and electricity invariably fails. Captain S. H. Wilkinson,[5] while recognising that there can be no more powerful source of suggestion of hysterical pain than pain due to organic causes, nevertheless succeeded by explanation and persuasion alone in curing many such cases as readily as the more obvious hysterical conditions. He found that long-continued treatment by drugs and other physical measures increased his difficulties, as their failure to cure merely tended to fix more profoundly than ever in the patient's mind the conviction of his incurability.

The following case is undoubtedly a case of hysterical perpetuation of pain.

CASE 9. *Injury to the back seven years ago; constant pain; doubtful X ray picture; hysterical perpetuation encouraged by wearing plaster jacket for four years.*—A labourer, aged 41, fell backwards on Dec. 28th, 1921, and hurt his back. He continued at full work until April 21st, when he gave up because of pain. Since then he has done no heavy work. X rays have been taken at various times and, while many of these have reported "nothing abnormal," others reported "fracture of the fifth lumbar spine." In consequence of this discrepancy a belt was ordered and, despite the fact that he could move freely, special exercises and massage were also given. In April, 1924, a plaster-of-Paris jacket was supplied by a surgeon who is stated to have remarked: "Unless you are careful, you will be an invalid for life." This jacket was kept on continuously for four years until removed by order of the Court in May, 1928. More X ray photographs were taken and the radiologist reported: "No evidence of injury or disease throughout the entire spinal column. Congenital condition of the spine of the fifth lumbar vertebra present." Contrary evidence was given that this was a fracture and also that some osteo-arthritis was present higher up, and the man was granted three months to recover without his jacket and recommended to try work after that time.

This case, I suggest, is one of hysterical perpetuation of pain, whether a fracture was originally present or not. Failure to cure depended largely on the unfortunate remark of the surgeon who applied the jacket and the prolonged wearing of the latter. A plaster support is no doubt a correct line of treatment for a few weeks until the fracture has healed, but continual application for four years is a disaster.

These few case notes are taken from recent examinations. Similar instances could be multiplied many times.

Treatment.

I have already hinted that the best treatment is preventive. Cases of accident should be carefully and fully examined at the earliest opportunity and an attempt made to form a correct diagnosis. Only in this way can the patient feel confident that nothing has been overlooked, while the doctor has the right to argue away the patient's fear of permanent incapacity. Too often radiographic examination is deferred for many months. If a fracture is found fixation or mechanical treatment is necessary. If no fracture is found the indications are to encourage movement. Undue rest in bed should be discouraged, and the patient taught to rely on his own efforts from the beginning. Too much stress should not be placed on treatment by massage and electricity, unless the patient is taught by the masseur to take an active interest in the proceedings. Hurst[6] relates how he has seen patients being massaged while reading a book or newspaper. Masseurs should have more tuition on the elements of psychotherapy.

I have never seen much benefit from the usual varieties of spinal support. It is impossible to assume that they are successful in causing fixation of the spine, but if they are applied they should be frequently changed and re-examination made. Prolonged treatment of fracture, joint injuries, and contusions by splints, plasters, and other methods of fixation often results in the adoption of a faulty posture or gait which can readily become permanent, as the muscles have adapted themselves to a new tonal length. Re-education is the only method of curing such disabilities and this, no doubt, is the result of the great success of bone-setting, osteopathy, and similar therapeutic measures.

It is obvious from the cases quoted that a little encouragement from the onset would have prevented months of incapacity. The man often believes that the sinews are destroyed or the nerve damaged, and desires his own doctor's assurance that his fears are without foundation. Such assurance is too seldom forthcoming. Only a medical man can diagnose between an hysterical and an organic paralysis. If no organic signs are present, then the paralysis exists because the man thinks he is paralysed, and he should be disabused of his idea and taught to use the affected muscles again. In the early stages the idea of disability is quite superficial and easily removed, but the longer it is allowed to persist and the longer psychological treatment is delayed the more deeply rooted becomes the suggestion and the more difficult to cure. In long-standing cases rapid recoveries are still possible under good conditions, but the general practitioner has lost his chance, and facilities for intensive treatment are difficult to obtain. Symns,[7] in an excellent paper, states that "no patient should be allowed to be in bed when he can be in a chair, and no case should be confined to a chair when he can walk." The doctor must continually stimulate the patient by his personality and energetic encouragement must be given at each visit. Too often is the bedside manner a name for a long countenance and another bottle of medicine. No doctor should be satisfied if his patient develops a paralysis—e.g., a dropped wrist, while the electrical reactions are shown to be normal; nor should a case be labelled hemiplegia if there are no signs of organic disease; nor should, in fact, any diagnosis but hysteria be made unless physical signs are present to support it.

The hysterical element must be looked for in all chronic diseases such as sciatica, rheumatoid arthritis, &c., and the practitioner will often be surprised at the wonderful recoveries which are possible, even after many years of pain and suffering. This hysterical element is probably present in all cases of chronic deafness, as most deaf people make little effort to listen. Even cases of complete blindness were cured in war time, after examination had shown that no organic disease was present and the optic nerve and tracts were intact—yet these had passed through the hands of several eye specialists without recognition of the functional element.

Once the condition is established, the cure requires time, enthusiasm, and confidence in oneself, and the difficulty in private practice is chiefly the lack of time. There is still need for special hospitals where whole-time medical officers can tackle these cases and where an "atmosphere of cure" can be developed. At Seale-Hayne Hospital, as no doubt in others during war time, the atmosphere of cure was encouraged. A patient coming into hospital with an hysterical condition was left for about two days before treatment was started. During this time the already cured cases in hospital would convince him that his recovery was certain and, as many of our cases were treated in the open in full view of the inmates, he would see for himself that such things did happen. A full examination was always made, and once we started to cure we were never satisfied until the cure was complete. A full explanation of the condition was given to the patient, showing how he had developed the idea of incapacity from his wound or injury. Encouragement was then given him to try to overcome his disability. In cases of flaccid paralysis, for example, he was encouraged to contract the weak muscles and his attention drawn to any slight flicker of the muscle which became apparent. In cases of spastic contracture he was taught to relax the contracted muscle. Both contraction and relaxation require voluntary effort on the part of the patient and reliance should not be placed on massage or electricity. No attempt at deep psycho-analysis is required. In some cases of hysteria this treatment is probably ideal, but it is not feasible for the busy general practitioner, and is generally quite unnecessary for the removal of symptoms.

The stages of treatment recommended are explanation, persuasion, and re-education. Under the latter term is included the correct use of the muscles, and it is well not to be satisfied with anything short of perfection. We found that if we stopped half way the ultimate stages were prolonged.

Occasionally, treatment went on for several hours, and in these cases a resistant patient eventually had to give way to a persistent doctor.

It has been written of hysteria: "The patient says—I cannot; the nurse says—he will not; the doctor says—he cannot will." I would suggest that this maxim is responsible for much of the apathy and neglect shown towards hysterical patients generally. The hysterical patient certainly can "will," but he has to be encouraged to do so, and failure to cure will most certainly result if he is treated as a malingerer. In Workmen's Compensation cases I have occasionally heard blame applied to the solicitors who are engaged in the man's interests, but no blame can be attributed to them. They cannot be expected to differentiate between an organic and an hysterical state. The blame must be accepted by the medical profession. There are very few conditions where the diagnosis offers great difficulty if a correct and full examination is made.

I must acknowledge my great indebtedness to Dr. A. F. Hurst for most of the teaching incorporated severe for two years, attributed to family worries, her health being good. The father's family had goitre, the family history being otherwise negative. Her eldest child was aged 8 and the younger 1½. It seemed possible that the first pregnancy at 27 was the starting-point of her ear trouble, the second causing exacerbation. Tinnitus, "like bells," was not severe, and she had no vertigo. Paracusis was well marked—volunteered statement. She never had earache or aural discharge; her voice was typically flat and toneless. She did not suffer from colds or catarrh, and her pharynx and nose were normal. The right tympanic membrane was slightly retracted, and the left showed cerise flush. T.F. 256; not heard by air; bone conduction much increased. Rinne: Very long negative. T.F. 32; no perception.

Parathyroid treatment started. After 4 weeks: "I feel better in myself." The hearing is definitely improved. After 13 weeks: Quite material improvement in hearing; no complaint of tinnitus (but this was not conspicuous before). The improvement in hearing has been remarked by patient, husband, and friends.

CASE 4.—A farmer, aged 28, came complaining of severe deafness beginning 12 years back—i.e., when 16. He had an operation on the nose at that time. His mother had been deaf since she was a young woman, and had been told that it was incurable and would not be improved by operation (almost certain otosclerosis). His own deafness became very much worse after severe influenza early in 1928; he had had a long course of inflation of the ears without benefit. Tinnitus was constant and severe in the right ear, sounding like "machinery," and in the left like "thumping." Nothing changed it. He had had one mild attack of vertigo recently and paracusis was well marked, but he never had aural discharge or pain. His general health was good and he did not catch cold. The Wassermann reaction was negative. His nose was normal with some post-nasal discharge, and the tympanic membranes were quite normal. He heard a shout at six inches with the right ear, but apparently nothing with the left. T.F. 256; definite diminution of bone conduction R. and L. Rinne: Long negative R. and L. T.F. 32; no perception at all. Upper tone limit practically normal.

Parathyroid treatment commenced. After 8 weeks: "I feel fine and have put on a stone." The hearing remarkably improved, observed by patient and relatives. After 13 weeks: The noises are inconspicuous, and the hearing still further improved; he is much encouraged. T.F. 256; bone conduction normal (? some prolongation.)

CASE 5.—A married woman of 38 came complaining of noises in the right ear, which began two months after an operation on her nose 18 months before; she also had recent slight deafness of both ears. Her family history was negative. The noises were constant, high pitched, unaffected by weather or anything else, and had not been improved by large doses of bromide or by regularly repeated aural inflations during 16 months. There was no paracusis (but the deafness was mild). She did not catch colds and never had aural discharge or pain or vertigo, but there was a constant feeling of heaviness in the head. Her nose showed rather a wide passage, with some post-operative atrophy, and excess of clear mucus everywhere. The tympanic membranes were retracted. T.F. 256; bone conduction increased R. and L. Rinne: Many seconds negative R. and L. T.F. 32; no perception.

Parathyroid treatment commenced; she was very sceptical of the results. After 14 weeks: "I'm much better. I feel better than I have for years." Both heaviness in head and noises have very materially diminished; hearing unchanged.

It is not claimed that the treatment is in any but an experimental stage, but it is simple, safe, and inexpensive and does not interfere with ordinary work. If only it leads others to investigate along the same lines, I trust that publication will not be considered premature.

A SCARCITY OF NURSES.—The East Suffolk and Ipswich Hospital is suffering from a scarcity of nurses. The recent epidemic of sickness affected so many nurses that one of the wards had to be closed, an event which has never happened before, and it still remains closed. Three years ago the period of training was reduced from four years to three; consequently the last of the nurses from the old, and the first from the new, period are completing their training simultaneously. The minimum age for the commencement of training has been reduced from 20 to 19. It has been impossible to open the maternity department for its proper work because it has been monopolised by motor accident cases. Complicated maternity cases are being treated in the gynæcological department.

SCHISTOSOMIASIS MANSONI.

BY DR. RAMESES GIRGES,
SURGEON, TANTA (EGYPT).

THE disease which is now known as *Schistosomiasis mansoni* is an endemic infection widely spread throughout Lower Egypt and in certain parts of Upper Egypt, and affects about one-quarter of the whole population. Tanta, where this study was made, is the centre of the largest endemic area of bilharziasis in the world. In over 4000 cases at my clinic I have noted two quite distinct types of the disease—viz., the intestinal and the hepatic—each of which runs its own course, presents definite stages, and has its special pathological lesions and clinical pictures, the one common feature being the presence of the *mansoni* worm. Even the ova, pathognomonic of this disease, are not constantly present; they are absent both in the first and fourth stages of the intestinal type and in the hepatic type. The latter is the more serious form of the infection. It is the condition known as Egyptian splenomegaly.

The intestinal type presents four stages—viz., febrile (toxæmic), dysenteric, papillomatous, and cirrhotic (repair). In fact the description of the disease as a dysentery is misleading; in only the second and third stages of the intestinal type do dysenteriform symptoms appear. Even so the patient seldom complains of dysentery, which is considered a natural event shared by most of the village folk. Furthermore, the hepatic type presents no dysenteric symptoms at all, but a toxæmic, a hepatomegalic, and an ascitic stage.

Epidemiology.—The disease is more frequent amongst villagers than in town inhabitants, and is almost limited to the fellaheen, fishermen, and fikies. It shows little preference for either sex, though more common in males. No age-period is free from it, but it is mostly found in the age-period 15–30. The infection occurs most often in the month of Baoonah (June).

Pathogenesis.—The cercariæ enter the body by piercing skin or mucous membrane, whence they reach the lymphatics and the general circulation, then the portal vein and liver. There they grow to the adult male and female worms. These events constitute the incubation period, and thus far the parasites inflict no apparent harm on the host. From the liver the adult females travel against the blood stream to their definitive position, the inferior mesenteric and middle and inferior hæmorrhoidal veins; during this passage they excrete toxins, for a febrile reaction in the host appears. This secondary migration is the main event provoking what I term the first or toxæmic stage.

The female in a venule in the intestinal submucosa lays her eggs very close to the intestinal lumen. By the action of digestive ferments elaborated by the embryos the eggs pass from the vessel to the surrounding intestinal wall. The postero-lateral spine of the ovum acts as a ratchet preventing it from returning into the vessel. The ova are thus gradually moved through the tissues until they are extruded into the gut lumen, and thence expelled from the body.

If the process were confined to this the disease would be benign. But in every case some of the ova fail to reach the gut lumen. A subacute inflammation is then set up by the mechanical irritation of the tissue by the ova and by the toxins they produce, and they become surrounded by leucocytes. If this "bilharziasis abscess" lies near the lumen of an intestinal gland it bursts and empties its contents into it. The damaged tissue rapidly heals and this process of egg-extrusion and abscess formation constitutes the second intestinal (dysenteric) stage. Multitudes of ova and a corresponding number of abscesses provoke a chronic diffuse inflammation of the mucosa and great epithelial proliferation. The adeno-papillomata thus formed characterise this, the third intestinal, or papillomatous stage. If the patient survive all this a fibroblastic reaction begins at the periphery of the unevacuated abscess, slowly advances towards the centre, and forms the "bilharzial pseudo-tubercle," in which the ovum is surrounded by definite nodules of fibrous tissue. The tubercle, scar formation, and contraction make up what I term the fourth intestinal or stage of cirrhosis repair.

This is the usual picture where male and female worms are present in more or less equal numbers. One sex only may be present, for the descendants of one miracidium are of one sex only—male or female. If the males markedly predominate or are the only sex present (the condition in most of my cases), there exists, besides the mechanical and irritative lesions, others which are purely toxic in nature. These cases show diffuse hepatitis, obviously not caused by ova, oviposition, or by coupling, but by toxins, either elaborated by the adult worms or provoked by their presence. The males when adult wait in the liver for the arrival of their females, and do not migrate to the mesenteric regions. The purpose of that journey, oviposition, is lacking for them. The worms in the body of the host provoke a partial immunity which prevents the arrival of new parasites to mate with those already in the liver, and so the case remains a hepatic bilharziasis, the intestinal lesions being negligible. This constitutes the so-called Egyptian splenomegaly, or what I term hepatic bilharziasis.

Intestinal Type.

My division of the course of intestinal bilharziasis into an incubation period and four stages is in accordance with its pathology. But symptoms characteristic of one stage may appear in other stages. Thus there may be fever side by side with oviposition in the second; oviposition with papillomata in the third, and both phenomena together with cirrhosis of tissues in the fourth. This is accounted for by the fact that the worm lives on an average for 15 to 20 years, the whole time producing lesions. Repeated infection, which could account for the phenomena, is, in my opinion, a negligible factor.

The *incubation period* lasts from three to five weeks, beginning with a few skin symptoms of variable intensity, partly mechanical and partly due to an irritating substance secreted by the cercariæ during their penetration of the skin. This "Baoonah itch" is commonest in the month of June. It is generally described by the patients as a biting sensation rather than an ordinary itch. It occurs in parts exposed to the water, and is followed by the appearance of small red papules 2–5 mm. in diameter, slightly raised above the level of the skin. Papules and itch remain for two to seven days.

The itch is more frequent when the water is stagnant and two to four hours before noon.

First Stage.—I have seen only 3 per cent. of my patients in this stage. It lasts from three to six weeks, and covers the time between the appearance of the first toxæmic fever and the extrusion of ova in the stools.

The onset may be acute, though generally insidious. About four weeks after infection the patient feels persistent headache, malaise in the late afternoon, followed by general muscular pain most marked in the lumbar region and limbs. The fever is remittent, septic, or hectic in type (erroneously called the "urticarial fever"). In some cases there are wheals, acute nephritis and œdema of feet, legs, and scrotum, occasional abdominal pain, a sense of distension, and generally lowered mentality. The wheals are the most important physical sign in this stage. They last from 12–24 hours, but are succeeded by others for 7–8 days. Slight cases manifest no digestive disturbance except occasional constipation, but some have diarrhœa. The abdomen is slightly retracted with rigidity of the muscles of the upper right quarter. There is tenderness, most intense in the region of the gall-bladder. The liver and spleen are enlarged, without exception, since the first week, mostly only slightly, but sometimes markedly so.

The pulse is slow and the blood pressure is usually subnormal. Areas of transient decreased resonance may be observed over the bases of the lungs, due to local œdema. The urine is scanty, dark coloured, of high specific gravity, contains albumin and a large number of granular casts. The blood picture is characteristic; anæmia of chlorotic type, leucocytosis 10,000–20,000 with 30–70 per cent. eosinophilia.

Second Intestinal or Dysenteric Stage.—The cases seen in this stage comprise 58 per cent. of the total number of my series. It is characterised by the presence of the ova in the stools, but without papillomata. Its duration is from two and a half to three years.

The effect upon the nervous system is seen in continuous malaise, indisposition for exertion, weakness, drowsiness, pain in the back, sawing pain in the whole body, and especially in the bones. During the night the patient experiences a sense of fatigue, uneasiness, heat, and sometimes fever. Bronchitis may be the most important symptom, and is accompanied in a few by hæmoptysis.

The patients suffer from anorexia, thirst, and sometimes pain in the epigastrium occurring shortly after meals. However, the most characteristic feature of the disease is an intestinal disturbance which I term schistosomiasis exacerbation. This begins with increased secretion of mucus, abdominal pain, and colic, followed by diarrhœa and tenesmus, with passage of blood and mucus. Attacks occur every 15–20 days and continue for a day or two. The patient when relieved becomes severely constipated for some time, although straining may continue. During the exacerbations all the patient's complaints are aggravated. Proctalgia is present in some and rectal prolapse occurs in one-quarter of the patients. In girls puberty and menstruation may be delayed up to the age of 20–22. In married women the uterus is infantile and the patient is generally sterile. The patients rapidly lose flesh and strength, especially those complaning of much fever or diarrhœa. The fever is a mild remittent type. There is tenderness all over the abdomen, especially in the middle line, ½–2 inches below the xyphoid process, over the cæcum, pelvic colon, and sigmoid. The liver shows a slight enlargement. The spleen can also be felt; its size slowly increases. No papillomata are felt per rectum. With the sigmoidoscope the mucous membrane can be seen deeply congested, velvety, bleeding, rugose, and covered with dense mucus. One of the characteristics of the fæces in this stage is the presence of blood and mucus outside the greater part of the stool, remaining on the top of the mass. This is the typical bilharzial stool, and is intermittently passed as long as the worms are actively ovipositing within the intestinal coats. Blood is present in the fæces in 92 per cent., while mucus was seen in 85 per cent. of my cases. The pulse is regular though quick and compressible. The blood pressure is normal, and the heart-beat is generally normal in character and position. There is chlorotic anæmia, with an average hæmoglobin of 62 per cent. The number of white blood corpuscles may be increased or remain normal. Eosinophilia is generally between 20 and 30 per cent. There is a subacute nephritis, with urine generally scanty, dark coloured, and of high specific gravity. In a quarter of my cases it contained albumin without any bilharzia ova; and in 11 per cent. casts, generally granular.

Third Intestinal or Papillomatous Stage.—The cases seen in this stage comprise 32·5 per cent. of my series. It is a continuation of the second stage with nearly similar symptoms, differing firstly in the formation of papillomata, and secondly in amelioration of the general symptoms due to increased personal tolerance for the disease. The exacerbations still occur every 15 to 20 days, but diarrhœa is present only in 16 per cent. Tenesmus is present in half of the patients and straining in one-third. Rectal prolapse occurs in 36 per cent.

The condition of the bilharziasis victim in the third stage is no better than in the second. The temperature is always below 38° C.; in 75 per cent. it is between 37° and 38° C., with a few pyretic paroxysms showing

458,916 red blood corpuscles per c.mm. of blood.[2] The average deficiency in percentage of hæmoglobin on admission was 11·654 per cent. for boys and on discharge 4·604 per cent., thus gaining 7·05 per cent. in the three months, and for the girls the average deficiency in percentage of hæmoglobin on admission was 14·234 per cent. and on discharge 5·555 per cent., thus showing a gain of 8·679 per cent.

These figures show a marked and very satisfactory improvement in the general nutrition and the condition of the blood, and show how quickly this type of child can be brought to nearly a normal state of health. In addition to the improvement as shown by the above figures children were better mentally and physically in every way, and teachers noticed that on their return to school their standard of intelligence was considerably increased. Instead of anxious and dull faces we have bright, smiling, alert countenances. They are more vivacious and happy, seeming to have a brighter outlook on life.

The scheme undoubtedly justifies itself in its beneficial results. The cost is inconsiderable, and there is every reason to believe that it will be more than recouped in the reduced cost of treatment of actual disease in the future. Meanwhile those who actually observe the youngsters under the regimen of the home are more—far more—than satisfied with the results.

In conclusion, I wish to thank Dr. S. G. Moore, medical officer of health for Huddersfield, for his kind assistance in allowing me to have access to his records and assistance in preparing this paper.

THE USE OF OX BONE PLATES AND SCREWS IN THE TREATMENT OF FRACTURES BY OPEN OPERATION.

By Hamilton Bailey, F.R.C.S. Eng.,
SURGEON TO THE DUDLEY-ROAD HOSPITAL, BIRMINGHAM.

Metal plates fixed by metal screws into living bone have proved to be unsatisfactory, because the metal, being a completely unphysiological substance, causes rarefaction of the bone. It is true that if the metal plate is removed as soon as union of the fracture has occurred these baneful effects are reduced to vanishing-point. Nevertheless, the removal of the plate necessitates a second anæsthetic, and there is a second wound to heal.

Plates and screws made of ox bone, which were introduced by Cunningham,[3] are assuredly much more physiological (Figs. 1 and 2). Once in place, they can be left alone; the plate and the screws are very gradually absorbed.

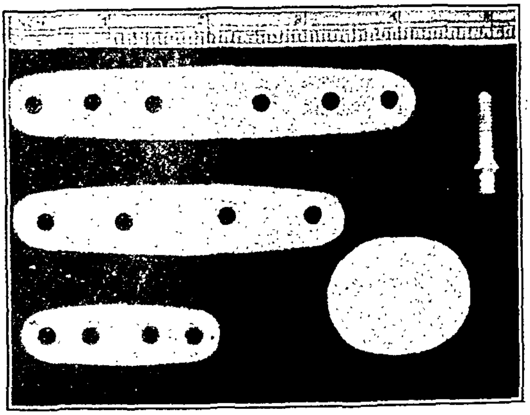
This note is based upon a series, occurring during the past four years, of 39 cases in which ox bone plates and screws were used. They were distributed as follows:—

Femur	13
Tibia	13
Ulna	4
Radius	2
Humerus	2
Skull (defect after trephining)	1
Spine (bolting together of lumbar spinous processes)	1
Separated epiphysis (bone screw)	3

The technique of inserting these plates is a little more complicated than that of inserting metal plates. It consists essentially of the following steps: (1) drilling the bone; (2) tapping the drill holes; (3) inserting the screws; and (4) nipping off the projecting handles of the screws. Certain technical difficulties have been encountered.

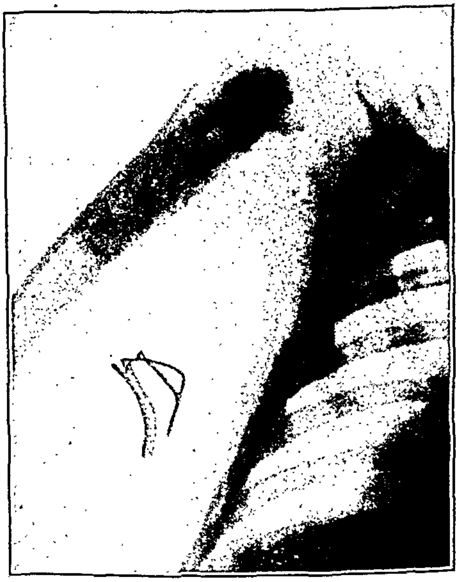
(*a*) *The thread of the tapped bone breaks.*—This is very provoking, and when it occurs, as the screws are of standard size, that particular hole is useless. Breaking of the thread is liable to occur in two stages of the operation. First, as the extremity of the tap enters the medullary cavity. This can be prevented by abstaining from any excessive downward pressure during the insertion of the tap. Secondly, a more fruitful source of this accident is in the endeavour to release the brace from the screw after the screw has been inserted. I found this such a constant source of trouble that I have given up using the brace, and have devised a pair of screw-driving forceps which can be released instantly (Fig. 3).

FIG. 1.



Ox bone plates, screw and disc of bone used for repair of trephine holes of skull.

FIG. 2.



A bone plate used in the operative treatment of a fractured humerus.

(*b*) *Breaking of the bone screw.*—I have had no trouble worth mentioning on this score, but a number of surgeons who are using ox bone plates complain that this is their chief difficulty. The fault, I am sure, lies not in the screws but with the tap. As a tool the tap of stainless steel supplied by surgical instrument makers is not to be compared with the Whitworth tap used in the metal trade. I find the most satisfactory method is to purchase a 3/16ths Whitworth

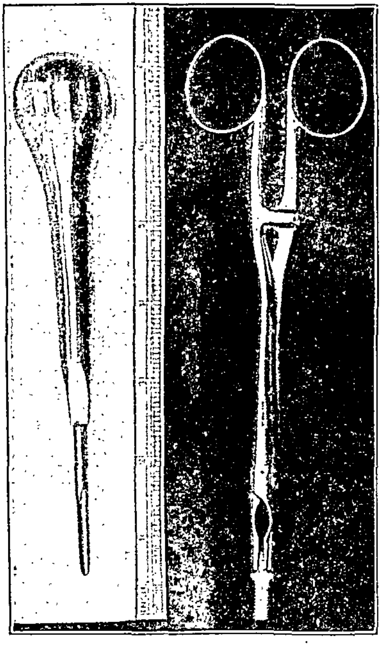
corpuscles ntific mean of the red blood corpuscle content of toxins, as nd for both sexes at age-periods for different races portal venules by established. For the purpose of this paper (nations elsewhere) I have taken 5,500,000 contraction of scar tie. For comparison only the method or splenic vein; and pig.

in Med. Jour., 1924, xxiii., No. 5.

tap from an ironmonger and have it riveted into a metal handle. Fig. 3 shows an instrument assembled in this way. Every six months the tap is changed because repeated boiling dulls its cutting edge. A hole properly tapped will take its screw without force, and we know that it is "home" when the screw-driving forceps free wheel around the projecting handle of the bone screw. Bone screws, unlike metal crews, *are driven with a light hand, for the necessary path* has been cut already by the tap.

FIG. 3.



The instrument on the left is a tap for use after the hole has been drilled in the bone. That on the right is a forceps-screwdriver holding a bone screw.

(c) *Fracture of the plate* has occurred twice in my series—once as the limb was being put into a Thomas's splint at the close of the operation, and once in the fourth week after operation, whilst the leg was being massaged. The first case is instructive, because it *serves to remind us how necessary it is to support* the limb fully during the application of the splint. After a tiring operation there is a tendency, as soon as the last stitch has been inserted, to leave this important step in the hands of others. Nevertheless, I believe that both these fractured plates were largely due to oversterilisation in their preparation. The plates and screws should not be placed in an autoclave, but boiled for 20 minutes on three successive days, and then stored in alcohol until required for use. Sterilised in this way, they should, with ordinary care, withstand the strain which they have to bear.

Perfect first-intention healing of the wound has occurred in all but two cases. In one case a sinus developed over the only metal screw which was used in the series. The use of the metal screw became necessary owing to the breaking of the thread of the tap in two consecutive holes—a difficulty which has already been alluded to, and which, I believe, is now finally overcome. The sinus quickly healed on removing the screw. In the second case (a complicated malunited fracture of the upper end of the femur, in which resection of a portion of the bone was necessary) a hæmatoma developed, which *became infected. This discharged for a month,* and then, fortunately, healed spontaneously, and at the present time (two years after the operation) there is excellent union of the femur and the wound.

In all cases the wounds have been closed by silkworm-*gut sutures only. No buried sutures of any kind* were used. The stitches were removed on the tenth day under personal supervision in the operating theatre.

For the femur I have used A. K. Henry's[*] method of exposure, which is a great improvement on the older methods. For the tibia a large external flap offers many advantages, and I am convinced that whenever possible the plate should not be placed upon the subcutaneous surface of the bone, but upon the external surface, where it can lie snugly concealed by the muscles of the anterior tibio-fibula compartment.

A FATAL CASE OF INFLUENZAL SEPTICÆMIA.

BY ANNE E. SOMERFORD, M.D. MANCH.,
D.P.H. CAMB.,
PATHOLOGIST TO THE ROYAL MANCHESTER CHILDREN'S HOSPITAL,
PENDLEBURY.

OWING to the rapid termination of the illness, and the fewness of the clinical and post-mortem findings, the following case seemed to be worthy of publication.

A well-nourished boy of two and a half years of age, with a history of diarrhœa and vomiting on the previous day, was seen at the out-patient department of the Royal Manchester Children's Hospital on March 22nd. The child appeared to be so gravely ill that he was admitted to hospital without delay. On examination a dusky purple discoloration (not a true cyanosis) of the skin was observed. The temperature was 102° F., the pulse-rate uncountable, and the respiration-rate 80. There were a few scattered râles over both lungs, but otherwise the clinical findings were negative. He had several slight convulsions, and died within an hour of admission to hospital. A post-mortem examination was made within 24 hours of death, but no lesion of any of the organs could be found. A culture was made from the blood within the liver, and this gave a good growth of Pfeiffer's bacillus of influenza, and a few colonies of *Staphylococcus albus.* Death was therefore due to a septicæmia of influenzal origin.

I have to thank Dr. J. F. Ward, at whose suggestion the culture was made, for his kind permission to publish the clinical notes.

A NEW MATERNITY HOSPITAL.—On Tuesday the Prime Minister opened the Lucy Baldwin Maternity Hospital at Stourport, Worcestershire, which has been erected as a model maternity unit for rural areas. The building, which stands high and overlooks the Severn Valley, consists of a main block and an isolation block. In addition to a ward of eight beds there is a private ward.

EDINBURGH HOSPITAL FOR CRIPPLED CHILDREN.—Two years ago it was decided to build an Edinburgh hospital for the treatment of cripples. A sum of £75,000 was asked for. At a meeting held recently in the City Chambers the Lord Provost reported that £50,000 has already been raised to this end, and that a site has been secured at Fairmilehead. The hospital is to provide not only for Edinburgh, but for the whole south-eastern area of Scotland and for the counties of Kinross and Clackmannan and the western half of Fife.

Medical Societies.

OPHTHALMOLOGICAL SOCIETY OF THE UNITED KINGDOM.

ANNUAL CONGRESS.

THE annual congress of this Society was held in London from April 11th to 13th under the presidency of Mr. Charles Howard Usher. The first contribution was a paper on

Formative Fibrous Tissue Reaction in the Eye,

by Mr. E. Treacher Collins. His purpose, he said, was to describe the form of reaction in the tissues of the eye which resulted in a new formation of fibrous tissue. He classified as follows the conditions giving rise to this reaction: (1) Encapsulating fibrosis. The first of the conditions under this head was in connexion with foreign bodies; the second in connexion with neoplasms, the third in connexion with parasitic cysts. (2) Post-fibrinous fibrosis in connexion with blood-clots. (3) Reparative fibrosis: (*a*) in connexion with developmental defects; (*b*) in the healing of wounds; (*c*) as a sequel of granulomatous inflammation.

In order to explain the conditions observed, Mr. Collins formulated the following general propositions: (1) That a formative fibrous tissue reaction was one of the means which the tissues of the body used for counteracting deleterious influences in their environment. (2) That such a formative fibrous tissue reaction might be excited, apart from any exudation of leucocytes, though at times associated with it. (3) That an aseptic foreign substance implanted in the body, exciting no exudation of leucocytes, might give rise to a formation of fibrous tissue which encapsuled and fixed it. (4) That all neoplasms when they came into contact with tissue of mesoblastic origin excited a formative fibrous tissue reaction, this tending to check their extension into surrounding parts. With slowly growing neoplasms it succeeded in encapsulating the new growth. With rapidly growing neoplasms the cell proliferation outpaced the formative fibrous tissue reaction, and the growth took on malignant characteristics. (5) That any remedial treatment of neoplasms should aim not only at checking the proliferative activity of the cells composing it, but also at promoting the formative fibrous tissue reaction. (6) That parasitic cysts coming into contact with tissue of mesoblastic origin excited a formative fibrous tissue reaction, an encapsulement in a fibrous tissue covering. (7) That coagulated blood in some situations in the body might act like a foreign substance and excite a formative fibrous tissue reaction. (8) That a formative fibrous tissue reaction might be excited in the repair of lesions in the tissues of the body, due to either defective development, traumatism, or a destructive inflammation. (9) That the new formation of fibrous tissue in the conjunctiva in trachoma was a secondary and reparative process which persisted, tending to replace the fibro-adenoid layer which was destroyed. (10) That the new formation of fibrous tissue in the conjunctiva in spring catarrh was a secondary reaction excited by the proliferation and downgrowth of the epithelium, and that it entirely disappeared when the disease came to an end.

Mr. F. A. Williamson-Noble read a paper on

Graded Squint Operations

in which he described his procedures for advancement of muscle according to the result of measurements. A point to remember was that if a convergent squint had lasted some time the external rectus became atrophic. He had been satisfied with the results of recession, or recession combined with tenectomy; he had not operated upon the external rectus alone. For measuring the angle of deviation he used the Maddox tangent scale or the Priestley Smith tape; but a better method was with the Maddox rod and prisms, graduated according to their angle of deviation. Mr. Williamson-Noble did the operation under general anæsthesia, as it was better for the patient and allowed of greater deliberation on the part of the operator. Of 16 cases which he had traced all but two were successful, and one of the failures could scarcely be called such, as she had 45° convergent squint before the operation, and it was reduced to one of 28°. The real failure was due to under-estimating the effect of Wilkinson's resection advancement.

Mr. M. L. Hepburn read a paper on

Some Unsolved Problems in Connexion with Diseases of the Choroid.

His first contention was that primary pigmentary degeneration of the retina was not due, as had been contended by Treacher Collins and others, to nerve degeneration (known as the abiotrophy theory), but to defects in the choroidal circulation. The next problem he attacked was that of the reason for the variations in the visual field defects found as a result of inflammatory deposits and scars in the choroid. He considered that main arteries supplying definite regions were isolated, and that an inflammatory deposit might block one of these main channels, and so produce the sector-shaped defect in the visual field. Next he dealt with the question why some diseases of the choroid terminated in secondary optic atrophy accompanied by a diminution in size of the retinal vessels, while in others, although the greater part of the choroid was involved, the disc and retinal vessels remained normal throughout. His impression was that vascular diseases of the choroid were more likely to end in optic atrophy than were the inflammatory forms. A further question which he discussed was the significance of the variations in amount and distribution of pigment in diseases of the choroid, and whether the appearance of this pigment bore any relation to diagnosis and prognosis. He thought it could safely be said that when pigment appeared away from its normal situation, in most cases one was dealing with a disease of the choroid, probably of inflammatory or vascular origin. Prognosis was not much helped by these appearances.

Mr. Treacher Collins discussed the paper at length.

Mr. Clark Souter reported a case of Uveo-parotid Fever, with Autopsy Findings. The patient was a man 40 years of age, and in addition to the general physical signs he had cycloplegia, dimness of vision, and facial paralysis. There was congestion of the conjunctiva and ciliary region, and permanent deposits of keratitis punctata were found all over the cornea. The latter persisted to the end.

Thursday afternoon was devoted to a debate on

HETEROPHORIA.

Dr. E. E. Maddox (Bournemouth) said that orthophoria, from which heterophoria was a departure, could be defined as "a tendency for the eyes to set themselves truly for the object of fixation." Heterophoria could well be compared to the slackness in the steering-gear of an old motor-car, which in moderate degree was of no consequence, but in larger amount made too great a demand on the subconscious attention of the driver. It was a corresponding tax on attention which gave to heterophoria its importance. Concentration of attention implied active inhibition of every conflicting neuron, Sherrington's "reciprocal innervation" in the motor sphere finding its counterpart in the psychic. The discomfort arising from heterophoria was apt to hover about the occipital region, whereas that of refractive errors was felt at the back of the eyes, in the temple, and the brow. Sometimes a wandering eye suppressed its vision instantaneously, so that no diplopia appeared; but, even so, the suppression made no difference to the effect of the wandering on the aim of the other eye. In one well-marked case, good binocular vision was enjoyed until the object came within two or three feet; then the right eye instantaneously suspended its vision and deviated without diplopia. There were 12 species of paretic heterophoria and 12 comitant. The measurement for the paretic was on the same principles as for frank paralysis. It was important to keep the disc of rods perpendicular to the line between the eye and the light; therefore he had strung one on a kind of gallows, so that it might remain quite vertical, however much askew the head might be placed. The comitant heterophorias were due, he said, to slackness of one of the higher conjugate innervations. Exophoria for distance was, nearly always, due to either subsidence of muscle tone or to convergence deficit. It was very rarely due to divergence excess. Division of the restiform body was said to cause conjugate version of the eyes to the opposite side, combined with elevation of one and depression of the other, confirming the see-saw innervations which the speaker had described in a case. Cyclophoria, if constant, was due to relative inaction of either incyclovergence (in which the two upper poles of the eyeballs approached one another) or excyclovergence (in which they separated). Dr. Verhoeff (of Boston) did not believe in cyclophoria, stating that the fusion of skew images with one another was effected by psychical means only. That was true, Dr. Maddox believed, within certain limits, but many tests showed that the eyeballs could rotate about their visual lines. He would like to see a case in which, in nystagmus, the eyeballs cycloverged in and out, as that would afford a further confirmation of the innervations he was referring to. The version phorias were less easily measured. Dextrophoria and lævophoria were due to imbalance of two innervations; in these conditions there was a tendency for the eyes to look parallel-wise to the right or to the left when at rest. Anaphoria and cataphoria meant a tendency for both eyes to look upwards or downwards, and were due to imbalance of the innervations he called surversion and deorversion. Students were often perplexed as between the terms "duction," "version," and "vergence." Whenever an eye was thought of monocularly one could speak of duction; it meant that an eye was led by its muscles, and the mind did not travel beyond the orbit. Version was a conjugate parallel motion of the eyes effected by conjugate innervations. Vergences were contrary reciprocal motions effected by conjugate innervations. Hence when measuring the amplitude of fusion by prisms it was better to speak of prism vergence tests than of duction tests.

Dr. Maddox then spoke of the tests for heterophoria. Since no refraction was complete without testing for heterophoria, it was desirable to have a speedy method to single out cases requiring more accurate measurement. It was convenient, he found, to have a hand trial frame which could be held in front of the ordinary trial frame, the former having rods on one side and a rotating prism or pair of prisms on the other. The prism could be rotated after telling the patient to say "snap" when the red streak and the light met. For accurate measurement a tangent scale was best, and if there was any suspicion that fusion was not completely suspended, one eye could be screened and then suddenly exposed to see where the streak appeared at the first moment of exposure. The wing-test he regarded as better, as it did away with the prism and ensured accommodation at the required distance.

Exophoria, by the wing test, was generally of trivial account, but esophoria called for a spherical correction which reduced it to nil. To give a weak prism for a large exophoria was often of great value, as it was the last degree of stretch of the fusion reflex which was most fatiguing. An approximate rule was, lenses for exophoria, prisms for exophoria.

Treatment.

It was impossible, said Dr. Maddox, to make rigid rules for the treatment of the condition, as it was a symptom not a disease. The person must be treated, not the phenomenon. Most minor heterophorias did not need treatment, though exceptions could be admitted in the cases of aviators, sportsmen, and others, as it might have importance when the nervous system was tired. The counsel of perfection was to ascertain the cause and, if possible, remove it. Errors of refraction were by far the most common cause, but septic foci in nose, teeth or tonsils, lack of fresh air and exercise, and anæmia could not be left out of account. If refraction treatment failed, the choice lay between exercises or relieving prisms. The former were more suitable for the young, prisms for the old. Any neurasthenia should be treated first. The effective value of a prism was less at reading distance than for a far object. Also, one must make sure that the hyperphoria was not an after-effect of wearing spectacles askew. If present only with the spectacles on, the fault lay with the glasses; if vice versa, the fault which had been in the spectacles was transferred to the eyes. Or the patient might have skewed his spectacles to correct it. For esophoria, prisms were less useful than lenses; the latter were curative. In exophoria, constitutional treatment was more often needed than in the other varieties; it was also the most suitable for training, especially where there was subconvergence. Weak prisms were often helpful; strong ones caused metamorphopsia, robbing the accommodation of the support it was accustomed to receive from convergence. Operations were very suitable in selected cases of heterophoria; in neurotic people there effect was not permanent.

Mr. CHARLES GOULDEN followed. He first described his routine examination of the muscle balance of patients who came with apparent or real refractive errors. Such an examination was obviously necessary. It was important to be certain of the type of deviation—i.e., whether it was concomitant or paralytic. The most important heterophoria was hyperphoria, a want of muscle balance between the eyes in the vertical direction; this form caused most inconvenience, because one had little power over the vertical deviation of the eye. Only when a vertical deviation caused symptoms should it be treated. Among the symptoms were persistent headache, often occipital, confusion of print, sometimes a complaint that lower lines of print surmounted upper lines. The treatment consisted in the use of prisms. If a low degree prism was necessary, this should be placed with the base down before the eye which tended to deviate upwards. If the prism needed was 2°, or more, it should be equally divided between the two eyes—i.e., one prism base down before the upward turning eye, the other base upwards before the downward turning eye. When of high degree, hyperphoria might call for operation; then advancement of either superior or inferior rectus should be done. He referred to four cases he had seen of torticollis due to hyperphoria. There were patients who, immediately the examination was commenced, had a spasm of convergence; these cases were probably hysterical in origin, and needed a careful correction of refraction, probably under atropine, and then such treatment as the hysteria might call for. He had neither operated nor supplied prisms for this condition. In cases which resisted treatment by exercise, especially those in whom an exophoria became a squint—i.e., when the patient was fatigued—operation might be necessary. Here tenotomy was not usually regarded as sufficient, there must be advancement of an internal rectus muscle.

Group-Captain E. C. CLEMENTS (R.A.F.) spoke of his experience in connexion with flying men, pointing out that in the case of an aeroplane in space, the strains and stresses differed from those in people on the ground. He analysed the results of spinning in the Barani chair 10 times in 20 seconds in the case of 118 men. Almost all flying men had good vision. He believed that a big percentage of cases of torticollis would be found to be suffering from hyperphoria.

Mr. Ernest Clarke did not think it was fair to take as normal the kind of case met with in the Air Force. In the ordinary population he regarded hyperphoria as very common indeed, but as it was usually of a minute degree, it was not important. For many years he had advocated the correction of low errors of refraction. When minus glasses were necessary there might be a small exophoria. The latter always lowered the amplitude of convergence, and when exophoria was present the fusion supplement required was always bigger, whereas it was for the ophthalmic surgeon to make the fusion supplement as low as possible. When low refractive errors were corrected, the hyperphoria usually disappeared in a short time. One should not be content with a single test. He objected to the use of prisms for young or middle-aged people; to supply these at this stage was a confession of weakness, and the strength had to be progressively increased.

Mr. H. B. Grimsdale spoke of the people occasionally seen who were greatly helped by a 0·25 cylinder and by a 1 prism. Could rules be laid down, he asked, for dealing with the condition? Probably not. For exophoria he usually advised exercises. He did not think the rôle of hyperphoria in the production of strabismus had been given sufficient attention. Cyclophoria rarely gave trouble.

Mr. Humphrey Neame agreed that in hyperphoria, to relieve the discomfort, the smallest possible prism should be used.

Mr. Harrison Butler said that often, when ordering prisms for elderly people with convergence insufficiency, the relief afforded tended to allow the muscles to repair, after which the prism could be discarded.

Mr. Williamson-Noble described this method of testing for cyclophoria by means of tilted mirrors.

After further discussion the openers replied.

On Friday morning Mr. W. S. Duke-Elder contributed a paper, illustrated by the epidiascope, on the

Nature of the Vitreous.

He said the vitreous was ordinarily conceived of as made up of a framework of fibres forming a close network, in the meshes of which was a fluid, the whole being kept in by a hyaloid membrane which surrounded the vitreous body. The fibrillar framework could be seen with the slit-lamp, though this could only show the optical appearances, the result of the heterogeneity of the tissues through which the light passed. The slit-lamp findings must be elucidated by an unequivocal source, and this was supplied by the ultra-microscope, which was first utilised in this study in 1923. Its magnifications showed the individual molecules, and no fixative was needed. The vitreous was found to be a pure homogeneous gel—i.e., of the consistency of gelatin. In a gel the water became absorbed by or combined with the colloid molecules; it had a high viscosity. On the surface of the vitreous were forces which aggregated together the micelle in close formation. In most cases the chemical composition of the vitreous was the same as that of the aqueous in regard to nitrogen and salt content; but in addition there was present a muco-protein to keep it transparent, and a kerato-protein to keep it gelable. Vitreous was derived largely from the ectoderm in the vitreous cavity. If the gel swelled glaucoma should occur; if it shrank there would be a tendency to retinal detachment. The sclerotic swelled in both alkaline and acid solutions, largely owing to its contained collogen. If the sclerotic swelled the volume of the eye was much diminished and the eye pressure rose enormously.

Sir John Parsons expressed high praise for this piece of research.

Among other papers at this sitting was one by Mr. Eugene Wolff on the

Pathology of Orbital Hæmorrhage and Inflammation.

Hæmorrhage into the orbit, he said, took a longer time to absorb than did bleeding into most other parts of the body, usually held to be because the orbital fat was relatively poorly supplied with blood-vessels. There was, however, another side to the question which had not received much attention. Clinically absorption of hæmorrhage was accompanied by swelling, but in the orbit the contents could only expand anteriorly, resulting in a pushing of the eye forward, thus manifesting itself as a proptosis. When the muscles of the eye had yielded to the full extent of their elasticity the orbit could be regarded as a closed space, and the œdema following absorption of hæmorrhage would cause venous obstruction, and, later, increased transudate. This would explain why orbital inflammation cleared up after a simple incision into orbital tissues without evacuation of pus. The rapid onset of blindness in many cases of orbital cellulitis was probably due to pressure exerted on the optic nerve or on its blood-supply. The indication in these cases therefore seemed to be to relieve the tension in the orbit, while doing a minimal injury to important structures. This thesis Mr. Wolff elaborated and quoted cases.

Mr. Maurice Whiting read a paper on

Optic Atrophy following Hæmorrhage from the Alimentary Tract.

He said that Harbridge found that 240 cases of the kind had been reported up to 1924. The present contribution consisted of records of three cases which had come under Mr. Whiting's own notice, and two others for which he was indebted to Mr. Hepburn and Mr. Doyne. The following could be taken as illustrative of them all.

A man, aged 40, was admitted to hospital in a semi-comatose condition. He had had abdominal pain, had two fits, and was very confused mentally. On admission he was very pale, the mucous membranes were blanched, and there was some jaundice. Soon after admission he passed two hard, black motions, but at the time the man was not thought to have melæna. Next day the motion showed a trace of blood. On August 14th the hæmoglobin index was 0·6, the red cells 15 per cent.; on the 30th the red cells were 19 per cent., and a month later the figure was 43 per cent. Both discs were pale and blurred, and there were small scattered patches of exudate round the discs. On Sept. 4th there was no perception of light in either eye.

The condition, said Mr. Whiting, might follow hæmorrhage from any source, but it was most commonly a sequel of bleeding in the alimentary tract or from the uterus. Many cases had occurred after childbirth or miscarriage, and only rarely after traumatic hæmorrhage. He did not believe the first ocular state was an optic neuritis; it was probably due, in his view, to sudden death of the nerve fibres.

Friday evening was devoted to a discussion on the

Diagnosis and Treatment of Ocular Tuberculosis.

Sir Arnold Lawson, in opening, said the differential diagnosis of tubercle in the eye might be said to rest on one or more of the following considerations: The presence of active tuberculosis elsewhere. In the eye tuberculosis was essentially a surgical rather than a medical condition. Ocular tuberculosis, as an accompaniment of phthisis, was very uncommon. Up to, and even after puberty, bovine, as opposed to human, tuberculosis was very common. Bovine tubercle needed a bovine test, as a negation of human tuberculosis did not exclude the bovine form. The possibility of mixed infection should never be forgotten; there was no reason against active tubercle coexisting with active mixed infection. In ocular tubercle there was an absence of subjective symptoms comparatively with objective signs. These cases were insidious in onset, destructive in character, slowly progressive, and intractable; there was a notable absence of severe pain. He opposed the use of

Calmette's local conjunctival test as being too dangerous. Tuberculous affections of the eye might be either extra-ocular or intra-ocular, the first of these being so-called primary or secondary. He doubted, however, whether tubercle, even of the conjunctiva, could ever be primary; it was certainly difficult to infect the conjunctiva unless a local abrasion was present. Intra-ocular tubercle was always a secondary infection; it might occur in any part of the uveal tract. The most common tuberculous inflammation of the eye was irido-cyclitis. Perhaps choroidal tubercle could not be diagnosed clinically at first sight. Tuberculous masses sometimes reached a great size without causing much trouble. They might disappear under the use of tuberculin. Treatment of ocular tuberculosis must be considered from the general and the local points of view, the former especially in the case of children with phlyctenular disease. In a large number of these benefit could not be expected until superabundant adenoids and enlarged tonsils had been removed. Of a series of 42 cases treated with tuberculin only 10 per cent. showed no improvement; in 45 per cent. healing followed its use. As, however, it might be a dangerous remedy, it should not be used unless it was quite clear that the case was suitable. Probably the value of bovine tuberculin was not yet fully appreciated. Much good had followed phototherapy for these cases, and he was able to endorse Mr. Duke-Elder's findings in this respect in the cases of children with phlyctenular disease. Sir Arnold had not found it of equal value for adults. This treatment should not be regarded as a substitute for, but rather as a supplement to, other methods. The question of the value of local ultra-violet rays was still sub judice.

Dr. R. A. **YOUNG** read a paper on the general systemic aspect of the disease. He said that if medical tuberculosis coexisted with the ocular condition the treatment of the latter must wait on the former. He was cautious in his treatment by tuberculin, using it in his lung cases only when the pulmonary lesions were stabilised and were not causing general symptoms. In the active stage of the disease both tuberculin and artificial sunlight could do harm.

Mr. S. H. **BROWNING** spoke on the subject first from the pathological aspect. As to treatment, he said he had been using bovine and human tuberculin for the eye for 15 years.

Mr. A. L. **WHITEHEAD** emphasised the importance of a thorough search of the whole body for tuberculous lesions when that disease in the eye was suspected. Many of the cases of vitreous hæmorrhage seen in which the cause was not very obvious he suspected of being tuberculous. He was a great believer in tuberculin, which should be begun very gradually.

Mr. **DUKE-ELDER** said he regarded phototherapy as merely an adjunct to ordinary treatment. It was extremely good in phlyctenular disease and other tuberculous diseases of the eye. In 33 cases at Moorfields in which the treatment was employed, the average period of treatment before phototherapy was adopted was two and a half years (75 per cent. had tuberculin injections also). In the period after the introduction of phototherapy 85 per cent. had a quiet eye after an average of five months' treatment; 6 per cent. were very much improved. In 9 per cent. the disease was still active at the end of that time, though there were hopes of much improvement.

Dr. G. **MACKAY** and Mr. M. S. **MAYOU** also took part in the discussion, and Sir **ARNOLD LAWSON** replied.

On Saturday morning Mr. **BERNARD CRIDLAND** opened a discussion on the

Prevention of Minor Eye Injuries in Industry.

He first spoke of the Departmental Committee on the subject in 1922, which gave an excellent survey of the whole question of accidents in industry. Four surgeons had supplied careful notes of eye injuries sustained in the course of occupations in 426 cases, the four being Mr. J. Evans (Birmingham), Mr. A. J. Ballantyne (Glasgow), Mr. R. J. Coulter (Newport, Mon.), and Mr. Cridland. The cases were divided into three main groups: (*a*) Occupations involving exposure to small flying particles, such as workers at grindstones or emery wheels. 51 per cent. of the cases were in this group. Risk of serious injury here was small, the trouble being mainly a foreign body in the cornea. (*b*) Occupations involving exposure to flying chips of metal, 26 per cent. of all. (*c*) Miscellaneous, including such occupations as mining, road-making and repairing, painting, plastering, general labouring, 23 per cent. In 70 per cent. of eye accident cases no form of protection to the eye was available—a fault of employers. In 19 per cent. protection was admitted to be available, but was not used. In the remaining 11 per cent. goggles or machine guards were used, therefore accident seemed to prove them inefficient. After pointing out the economical loss of failure to adopt measures of protection, Mr. Cridland said there were three main lines of prevention—namely, those based upon (1) mechanical guarding; (2) education on the subject of workmen and foremen; (3) engineering revision. Good goggles, he said, gave 100 per cent. protection, shields 90 per cent. protection. The great obstacle to success in all these efforts was the objection of the worker to the wearing of goggles, many regarding them as effeminate.

Mr. J. H. **FISHER** pointed out that the Council of British Ophthalmologists had been actively interested in the same subject. Mr. **TREACHER COLLINS** thought a visor on the lines devised by Sir Richard Cruise for war purposes, with a very fine mesh, might be used; it would be better ventilated than glass goggles. Mr. **JOHN ROWAN**, Mr. **CYRIL WALKER**, Mr. J. F. **CUNNINGHAM**, Mr. M. **HINE**, Dr. G. **MACKAY**, and Mr. A. L. **WHITEHEAD** also discussed the subject, and Sir **JOHN PARSONS** pointed out that American employers in engineering shops took a stronger line than British employers in insisting on workmen using adequate protection.

On Friday afternoon clinical cases were inspected and discussed at the new premises of the Royal Westminster Ophthalmic Hospital. During the congress two rooms were set apart as a museum of ophthalmic appliances, drawings, and literature, the exhibits including goggles damaged during use at various trades.

LONDON ASSOCIATION OF MEDICAL WOMEN'S FEDERATION.

AT a meeting on March 26th Miss F. M. **HUXLEY** took the chair, and an address on

Pain in Relation to Lesions of the Upper Urinary Tract

was given by Miss E. C. **LEWIS**. She distinguished three varieties of abdominal pain caused by lesions of the kidney and ureter: (1) colic; (2) pain in the loin and midaxillary region, due to lesions of the parenchyma; and (3) pain at the outer edge of the rectus abdominis, at the umbilical level, caused by distension of the pelvis. Colic in its most severe form was caused by a stone in the renal pelvis or ureter. Some writers thought that it was due to tension of the kidney capsule, others that it was a spasm of the unstriped muscle. Legueu's work on pyeloscopy seemed to support the view that there would be painful and vigorous contractions behind an obstruction, just as in the alimentary canal. Oddly enough, stones in the calices did not cause pain. Renal colic, however, did not always indicate the presence of a stone; similar attacks, though usually less severe, were caused by the passage of other foreign bodies, such as blood clots from a malignant growth, débris from a tuberculous kidney, or "showers" of crystals; also by irregular spasms in acute pyelitis, and ureteritis, and in Dietl's crises, and crises of nervous origin. The differential diagnosis included biliary and appendicular colics and those of intestinal and pancreatic origin. The radiation of urinary colic was fairly characteristic. The other varieties of pain were more difficult to diagnose; they were often not particularly characteristic of the kidney, and gave no help in distinguishing between the different kinds of renal lesion. A heavy aching pain, often accompanied by tenderness, was associated with large kidney stones, and with ureteric stones impacted above a stricture or with those too large or lying too obliquely to be passed on; in these cases the patient was often unable to lie on the affected side. There were exacerbations due to superimposed attacks of pyelonephritis. A stone impacted in the lower end of the ureter caused vesical pain and frequency. In hydronephrosis, which was merely the evidence of obstruction to the outflow of the kidney, there was aching pain from distension of the pelvis and parenchyma, and, in large tumours, from dragging on the nerves of the pedicle and surrounding structures. Often the smaller distensions were the most painful. A great number of movable and dropped kidneys were symptomless, and required no treatment; others gave varying manifestations, nervous, or referable to the digestive system, including the curious one of jaundice when the affected kidney was on the right side; some caused renal obstruction and infection, with pain, either aching or colicky. Tuberculosis and malignant growths were almost negligible in differential diagnosis, the former because the slight aching in the loin was overshadowed by the bladder picture, and the latter because pain did not occur by itself, but was a late symptom, hæmaturia being the early one.

The simple acute infections were perhaps the most difficult to diagnose and deal with. The milder ones might be painless; often there was tenderness without pain. In more severe cases pain and tenderness in the loin, accompanied by fever, were the dominating features. In the fulminating cases the picture was more that of an acute abdomen. The spasms, strictures, and kinks of the ureter had received more attention in America than in this country. According to Hunner they gave rise to protean manifestations. The pain, when present, was felt in the lower abdominal quadrant, since the lesion was generally situated in the last few inches of the ureter. There might be tenderness where it crossed the brim of the pelvis, and also below the broad ligament. The pain was apt to be intermittent; some patients were only troubled at night, some by day, others in the early morning. There might be a free interval lasting for months. In 75 per cent. the picture was that of irritability of the bladder. The accompanying kidney manifestations were those of the distension and infections caused by the obstruction. Unfortunately, examination of the urine was not always helpful, as it was said to be normal in 30 per cent of these cases.

In differential diagnosis of the chronic types of pain lesions of the upper digestive tract need not be considered, since here there was no relation of pain to the taking of food. Acute perinephritis began just like acute renal infection, but the urine contained no pus, and kidney function was unimpaired. An inflamed gall-bladder was usually tender to pressure beneath the costal margin during deep inspiration. The pain of an appendix was rather more lateral than that of the ureter, and did not radiate in the same way. A lesion low enough in the ureter to simulate one in the uterine appendages would cause frequency. Calcified mesenteric glands must be remembered, and also radiation along the lower dorsal nerves, secondary to spinal or thoracic diseases.

BRIGHTON AND SUSSEX MEDICO-CHIRURGICAL SOCIETY.

An Alternative to Wheelhouse's Operation.

At a meeting of this Society on April 4th, with Mr. Geoffrey Bate, the President, in the chair, a paper on Retention of Urine was read by Mr. H. J. McCurrich. This condition, he said, might easily be overlooked when present, or diagnosed when absent. The former error was due to mistaking retention of urine with overflow for retention of urine; the latter to a failure to diagnose suppression of urine. A catheter would solve the difficulty, and should always be used before a diagnosis of incontinence was made. Mr. McCurrich had seen a patient who had been placed in seclusion as a case of mania. The real trouble was uræmia and retention of urine due to an enlarged prostate; his retention of urine with overflow had been mistaken for incontinence. In partial retention of urine, residual urine remained after micturition, and its amount indicated the degree of obstruction or the weakness of the bladder.

After a historical survey of the subject, and a consideration of causes, Mr. McCurrich concluded his paper with a discussion of operative measures. External urethrotomy, he said, apart from puncture for the relief of retention, dated from the early part of the nineteenth century, and in this country was associated with the names of Guthrie and Syme and, later, Wheelhouse. The disadvantage of Wheelhouse's operation was that great difficulty might be experienced in finding the way through the stricture when the urethra in front of it was opened. He had therefore devised the following operation.

> The patient is anæsthetised spinally and placed in the lithotomy position. The bladder is opened suprapubically by a small incision into which is introduced a finger, and along this a sound is passed into the internal urinary meatus and along the prostatic urethra. Another sound is passed through the external urinary meatus along the anterior urethra. The tips of the sounds are then only separated by the stricture; a perineal incision on to the tops of the sounds divides the stricture. The tips of the sounds are exposed; the anterior one is rotated to extrude its tip. Each end of a piece of rubber tubing about the size of a No. 12 catheter is tied on to the sounds, a long window being cut close to the end of the one tied to the posterior sound. The sounds are withdrawn by the way they entered, the tube is drawn in with them, so that it traverses the urethra and bladder; each end of the tube is secured by a safety pin, so that, however restless and uræmic the patient is, there is little risk of his extracting the tube.

Each day, said Mr. McCurrich, the tube might be moved to and fro by means of the pin at each end, and in this way the urethritis associated with an indwelling catheter was diminished. The tube might be left in up to a few days or a week. The subsequent treatment and dilatation were the same as for a Wheelhouse operation. He had performed this operation first in 1925 and had done it twice since. The fact that the tube traversed the suprapubic wound did not delay healing.

DEVON AND EXETER MEDICO-CHIRURGICAL SOCIETY.

At a meeting of this Society held on March 28th, with Dr. Bertram Cohen, the President, in the chair, a paper on eight cases of

Acute Intussusception in Infants

was read by Dr. J. Douglas Murray. There were four patients, two of whom had one attack of intussusception each, whilst the other two had three attacks each. The cases occurred, he said, during a period of 13 months, and all four patients were males, healthy and robust, between 3 and 22 months of age. Six of the attacks occurred in children under 12 months' old, and these were breast-fed, except one child which was being weaned during the week before the onset of acute symptoms. Dr. Murray called attention to the fact that information about the ordinary food of the infant is rarely forthcoming in the notes of hospital cases, owing to the acuteness of the condition and the desire to remedy it as soon as possible after the child's admission. In the case of the children under 12 months of age careful inquiries about diet were made at the time of admission, and dietetic errors or alterations were proved in each instance in spite of the mother's statement that the child was breast-fed. Inquiries by Fitzwilliams into the seasonal incidence of the disease showed that the maximal number of cases occurred in March and December, and that there was a steady decline in the incidence of intussusception during the summer and early autumn months when epidemic diarrhœa was most rampant. Also the majority of cases of epidemic diarrhœa occurred in children who were artificially fed, whereas acute intussusceptions were most often seen in healthy, breast-fed children. There seemed, therefore, to be no justification for regarding acute enteritis as a predisposing cause of acute intussusception.

Dr. Murray said that two of his patients had died, each with hyperpyrexia; in both these cases, and in these two cases only, could the intussusception be felt per rectum. The other two children recovered, each of them having three intussusceptions during the period of 13 months; there was never less than four months' interval between one intussusception and the next. In each case treatment was by laparotomy, with manipulative reduction of the intussusception. Dr. Murray discussed the non-operative treatment of this condition, and mentioned that uncertainty as to whether there was complete reduction of the intussusception seemed to be an insuperable drawback to this line of treatment. He concluded by considering the ætiology of the condition, and said that he regarded hypertrophy of the lymphoid tissue in the lower end of the ileum, consequent upon intestinal irritation produced as a result of some error in diet, as the chief cause of acute intussusception in infants.

The **President** mentioned two cases of which he had had personal experience. In the first the stools passed immediately after reduction contained a stub of asparagus. In the second the last portion could not be reduced and had to be opened up. An inflamed appendix containing pus was found inside.

Mr. A. L. **Candler** said that in his opinion elongated mesentery was the primary cause and that dietetic errors provided the stimulus. As regards diagnosis, he emphasised the importance of emptiness in the right iliac fossa and stated that in some cases the lump could not be felt without an anæsthetic because it was high up under the liver or lower ribs, but that under an anæsthetic the hand could be pushed up higher and the lump palpated.

Mr. N. F. **Lock** drew attention to the lessened incidence of acute intussusception.

Mr. R. **Wayland Smith** was of opinion that if a change of diet, or dietary indiscretion, was the cause of intussusception, a much higher incidence of cases would be expected, and agreed with Mr. Candler that the underlying condition which made an ileo-cæcal intussusception possible was a congenitally long mesentery.

In his reply Dr. **Murray** said that the cause of intussusception was a moot point, but agreed that the most probable cause was an error of diet in children with an abnormally long mesentery. He thought that the "signe de Dance" was of doubtful value.

Southend General Hospital.—It has now been decided to proceed with the first portion of the proposed new hospital at Southend-on-Sea. This section, which will cost £111,000, will contain 164 beds, 40 of which will be for children, and others for paying patients. It will also include a nurses' home with accommodation for 60 nurses.

Queen's Hospital, Birmingham.—It was stated at the annual meeting of this hospital that 15,386 casualties were treated last year, and that ten beds have now been endowed by the efforts of the university students. On behalf of the medical staff the need was emphasised for a supply of radium, and for the provision of beds for paying patients.

Reviews and Notices of Books.

RECENT ADVANCES IN NEUROLOGY.

By W. **Russell Brain**, D.M. Oxf., M.R.C.P. Lond., Assistant Physician to the London Hospital; and E. B. **Strauss**, B.M. Oxf., M.R.C.P. Lond., Medical Registrar to the Hospital for Epilepsy and Paralysis, Maida Vale. With 38 illustrations. London: J. and A. Churchill. 1929. Pp. 412. 12*s.* 6*d.*

This addition to the "Recent Advances" series makes excellent reading. In the last few years so much attention has been given to neurological research that the problem of what to omit must have been even more difficult to solve than that of what to include. In their range of selection the authors have been catholic enough for all minds, seeing that the matters discussed include, to mention but a few, questions of the cerebro-spinal fluid, neurotropic viruses, classification of cerebral tumours, conditioned reflexes, posture and tonus, X ray treatment of nervous diseases. In other words, physiologist, neuropathologist, clinician, and therapeutist alike will here find something of value for themselves. In one or two passages suspension of judgment might have been adopted. The statement, "it must now be regarded as established that the anatomical basis of encephalitic Parkinsonism is a lesion of the substantia nigra," reads curiously when, on the next page, we are informed that "the anatomical site of the lesion in paralysis agitans is more problematical." Further, these remarks leave untouched the question of whether, on other grounds altogether, a lesion of the substantia nigra is sufficient for the manifold semiology of that state. Again, it is inaccurate to say that the symptoms of "circus movements, difficulty in taking food, chewing and swallowing, voice disturbance, hypertonicity, tremor, athetoid movements, and constriction of the pupil," produced experimentally by striatal lesions in cats, "correspond strikingly" with those of hepatolenticular degeneration; some do, others assuredly do not. In some instances, again, the views of authors have not been reproduced with precision. But, on the whole, little complaint will be made by the many authorities whose work is summarised. Nor does perusal of the volume leave the impression of a mere réchauffé of the work of others; a book of this kind must contain numerous references to, and descriptions of, the investigations of neurologists, but these are here subjected to a careful sifting process; in passing through the minds of the two authors they have been freed from non-essentials and given a place in a general setting so that they can be appreciated at their true worth. This task must indeed have been far from easy, and we congratulate the writers on its efficient accomplishment.

NEUROBIOTAXIS.

Three Lectures on Neurobiotaxis and other Subjects. Delivered at the University of Copenhagen. By C. U. **Ariens Kappers**, Amsterdam. London: William Heinemann (Medical Books), Ltd. 1928. Pp. 76. 7*s.* 6*d.*

Three lectures, reprinted from the *Acta Psychiatrica et Neurologica*, are here published in convenient form, and deserve the neurologist's attention. Dr. Kappers is the exponent of that "psychical" law in the structure of the nervous system which he has called neurobiotaxis; in these pages its nature and mode of working are clearly and succinctly described. The second lecture deals with the corpus striatum from the standpoint of comparative anatomy and physiology; the third, with the development of the cortex and the functions of its different layers. Each subject is handled in a masterly way. Dr. Kappers doubts whether the highest development of the corpus striatum is found in man; compared with the brain-stem its size is larger in some of the lower animals. He shows that in the archicortex there is a general differentiation into two layers only—a granular receptive layer near the surface where most afferent impulses run, and a deeper (subgranular) efferent pyramidal layer. In addition to these two, the neocortex possesses a third or supragranular layer, whose development distinguishes the higher levels in the animal series, and is a consequence of increase of corticipetal and associative fibres.

Tweedy's Practical Obstetrics.

Sixth edition. Edited and largely rewritten by Bethel Solomons, M.D., F.R.C.P.I., Master, Rotunda Hospital. London: Humphrey Milford, Oxford University Press. 1929. Pp. 759. 25s.

This book, for 20 years well known and greatly appreciated, appears now in a slightly extended form under the guiding hand of the present Master of the Rotunda, who collaborated with Dr. Tweedy in the previous edition. Now solely responsible, Dr. Solomons has impressed his style and teaching on a work which always had a character of its own and has made the blend of the old Master and the new into a wonderfully uniform composite production. Doubtless amalgamation was simplified by the close relationship of teacher and pupil and by the fact that the book represents the practice of one great hospital in which both have served and in whose traditions both are versed.

Dr. Tweedy's original aim was to fill blanks in the practical knowledge of the recently qualified, and he omitted "all that is theoretical and not immediately useful to the practitioner." Dr. Solomons has wisely added an introductory portion contributed by Prof. Bronté Gatenby on anatomy and embryology, and himself has inserted the physiological matter necessary to open the appropriate chapters in Part II., covering normal pregnancy, labour, and puerperium. Part III., on abnormal pregnancy, begins with a chapter on toxæmia, and here the new author has allowed himself almost too complete an absolution from the restrictions of the title and original purpose of the book, and has devoted some few pages to theory before he gets down to the practical aspects of his subject. When he does so descend, however, he gives a clear and exhaustive account of the Rotunda method of treating eclampsia. Here he insists on "the necessity of paying the very strictest attention to every detail of this treatment," and in support of this injunction can point to the excellent results obtained in his hospital.

It is interesting to note a few changes that have come from a review of further experience of the methods recommended in previous editions. In accidental hæmorrhage the old Rotunda method of vaginal plugging, so strongly advocated by Tweedy, is now rarely employed and is reserved for cases in which the simpler treatment now advised fails to curtail bleeding and signs of collapse persist. Submammary saline infusion, rupture of the membranes, and injection of pituitary extract form the basis of the treatment now adopted. Another subject on which views have been reconsidered is uterine inertia, since, like many others, Dr. Solomons has found difficulty in fitting his cases into the types commonly described as primary and secondary, and in explaining the causes of these types, or as he says, "in determining whether there is anything outside the uterus making it inert." We doubt whether his vague conceptions of the primary form as being due to weak nerve-impulse, weak muscle, or hormonic cause will be found helpful. From the wide prevalence of rickets in Dublin, it follows that the chapter on pelvic disproportion is complete and practical and full of sound clinical experience. The Cæsarean section operation, much too often performed by those without adequate knowledge of alternative procedures, is here put into its proper place, and for conditions other than pelvic disproportion its adoption is also strictly limited. It has been wholly abandoned for accidental hæmorrhage, and is rarely used in placenta prævia.

Dr. Solomons disdains the dicta of tradition and authority if they do not accord with his clinical experience, but is at times himself dogmatic—no fault in a teacher. Thus, though its character has been somewhat changed, this work is as interesting as it ever was and fully maintains its individual distinction. It is a remarkable tribute to the great hospital whose methods are given deservedly wide prominence in its pages.

Elementary Hygiene for Nurses.

Fourth edition. By H. C. R. Darling, M.D. Lond., F.R.C.S. Eng., Surgeon, Coast Hospital, and Lidcombe State Hospital, Sydney, N.S.W. London: J. and A. Churchill. 1929. Pp. 292. 5s.

Apart from the title and the statement in the original preface that "this work is primarily addressed to nurses," there is little about it to indicate its special suitability for nurses reading for their final examination. The book is not in any way confined to the principles of hygiene or written in simple language, and the matter is largely similar to that contained in public health text-books designed for medical graduates studying for the diploma of public health. The fact that so much has been compressed into a small space does not make for clarity, and, indeed, causes the matter to be more difficult of digestion than that contained in the larger text-books, which have more space for explanation.

Parasitology.

Travaux pratiques de parasitologie. By E. Brumpt and Neveu-Lemaire. Paris: Masson et Cie. 1929. Pp. 302. With 202 figures. Fr.30.

The importance of parasitology increases each year, and it is becoming more and more obvious that extensive practical instruction should be an integral part of every student's curriculum. Several excellent text-books on the theoretical aspect of the subject exist—notably one by Prof. E. Brumpt, of Paris. The need for a practical text-book on the subject has now been met by Brumpt and Neveu-Lemaire of the Department of Parasitology of the Paris Faculty of Medicine. In some 300 pages they cover the ground necessary for such a course, dealing not only with the parasites proper, but also with medical entomology, mycology, and with the zoological aspects of the various intermediate hosts. The book is well conceived, well written, and fully illustrated, and should prove an excellent and reliable companion to every student of the subject.

Catalytic Processes in Applied Chemistry.

By T. P. Hilditch, D.Sc., F.I.C., Professor of Industrial Chemistry in the University of Liverpool. London: Chapman and Hall, Ltd. 1929. Pp. 360. 16s.

One of the outstanding modern tendencies in manufacturing chemistry is the increased attention being paid to the development of catalytic processes. This book is addressed to those already acquainted with one or more phases of catalyst technology, and to others who may desire to apply catalytic action to manufacturing problems in which it has not previously been employed. The book is divided into four sections, dealing with the general principles of catalytic action, catalysis at the surface of solid inorganic materials, catalysis at surface of colloidal organic compounds—i.e., fermentations—and homogeneous catalysis in liquid systems. This method of classification enables the author to create order out of chaos and to cover successfully a very large range of widely differing processes. The style is throughout clear and interesting and reveals a detailed knowledge of the processes described.

THE LANCET.

LONDON: SATURDAY, APRIL 20, 1929.

CONDITIONED REFLEXES.

ONLY in the last year or two has the work of Prof. IVAN PAVLOV, of Leningrad, aroused that widespread physiological and general interest which its remarkable character deserves. For the major part of his long lifetime he has, with singular constancy, devoted himself to the study of problems arising from the curious phenomena of what he terms the "conditioned reflex," but his published contributions have been, with few exceptions, restricted to the Russian language. It is therefore a matter of importance for the English reader to have in his hands a complete reprint of all these papers, excellently translated, of which the first is dated 1903, and the last (of 41) 1928. Moreover, the translator, Dr. HORSLEY GANTT, gives us a biographical sketch of the veteran physiologist which brings the man before us in graphic fashion and enables us to understand better his single-minded enthusiasm for the child of his brain. For it can scarcely be questioned that the association of PAVLOV with conditioned reflexes will remain as historical a combination as that of DARWIN and evolution.

With the assistance of something like one hundred collaborators in the course of these fruitful years, uninterrupted even by war and revolution, Prof. PAVLOV has probed ever deeper into the problems of cerebral function, and is at length in a position not only to add materially to knowledge of neural mechanisms, but to throw much-needed physiological light on the nature of not a few processes commonly considered to be essentially psychical. His results have been obtained by strictly objective methods, the subjective factor being completely eliminated by a technique the details of which are almost as fascinating as their application. For a basis two varieties of reflex have been utilised—the unconditional and the conditional. The former is innate, permanent, invariable; that employed throughout (the dog being the experimental animal) is the salivary reflex—viz., when the buccal cavity is stimulated by the insertion either of food or of acid, a reflex flow of saliva occurs, which can be measured with exactitude. Now a similar secretion can be readily excited if food is merely shown to the animal; the salivary centres can be reached by extrinsic stimuli of a visual kind; and if food is administered at the same time as a stimulus of still another kind—for example, auditory or cutaneous—then by dint of sufficient repetition these stimuli in their turn will evoke the salivary reflex by themselves. That is to say, properties which bear no direct relation whatever to the physiological rôle of the saliva can be made to act as stimuli—for example, form, colour, tactile and painful sensations. Excitations of this kind are dependent on a number of conditions, and are described as "conditional," or, more usually, "conditioned." The reflex which they elicit is a "conditioned" reflex; it is temporary, acquired, and modifiable. By numerous experiments Prof. PAVLOV has proved that the locus of conditioned reflexes is cerebral; for their appearance integrity of the cerebral hemispheres is a sine qua non. Any stimulus of any kind (and their number is legion) can be utilised for the purpose; it can be made into a signal, and from its receptor centre there must evidently be an open physiological path to the salivary nuclei. If eye, ear, nose, or skin is affected by any imaginable phenomenon of an excitatory kind, this can be turned into a conditioned stimulus and can arouse a conditioned reflex. And these statements are to be taken literally; the experimenter's voice, accents, appearance, clothes, his handling of the animal, his touches, caresses, the sound of his step, his *parfume humaine* (in one striking instance his garments by themselves)—one and all form the material for conditioned salivary secretion. "He" is, in point of physiological fact, an external synthetic stimulus. On this ground alone, although also on others, it may justifiably be claimed that a series of stimuli commonly thought to be of a psychical order act precisely and invariably, under conditions, as do intrinsic physiological stimuli.

In the higher parts of the nervous system, then, there exists a potentiality for temporary coupling of conduction paths, a universality of possible connexions, which serves to illumine cerebral function in an impressive way. Evidently these possibilities are infinite; according to JUDSON HERRICK, the number of possible connexions of two neurones in the human brain is $10^{2,783,000}$. There can be no end to conditioned reflexes, which means, in other words, that the human brain is never at an end; probably no one ever uses anything else than a fraction of his cerebral endowment. It is an organ of immense plasticity, capable of new acquisitions, even if temporary, as long as it lives. A corollary of this modifiability must be that there is comparatively little of the cerebral cortex that is organised, and in which specific centres can be placed. While Prof. PAVLOV accepts an anatomical cortical site for the receptive fields of the senses, and though he certainly regards the cortex as a mosaic of function, he does not overlook the implication of his experiments in so far as they demonstrate possibilities of compensation and substitution. For him, that function is constituted by stimulation and inhibition, and by irradiation or, alternatively, by concentration, of each of these; there is nothing else. He has found no trace of any "higher" function; and he reduces the complexities of the most elaborate cerebration or mentation to combinations of conditioned reflexes. He speaks of the reflex of "freedom," of "purpose," of "slavery," of "defence," of "collecting," of "sleep," nay, of "life" itself. Nor is this a mere *façon de parler*; it is a legitimate inference from the behaviour of his animals under the strictest scientific technique in the experimental room. The dog, by means of his cerebrum and its sense centres (or "analysers") decomposes the whole complexity of the external world into its units; he uses a synthesising mechanism and an analysing mechanism. Thus he makes a perfect adjustment, ensures a perfect equilibration, and there is every reason to believe man does the same. Training, education, habits, orientations in the external world, with all its events, natural and social—what are these in the last resort but either a formation of new connexions, or a superfine analysis?

Of the many-sided nature of Prof. PAVLOV's general conclusions the reader will soon convince himself. It is already widely recognised that he has explained the phenomenon of sleep in a manner more consonant with the facts than any previous hypothesis. Sleep is nothing else than internal inhibition; a stimulus which ordinarily awakens a conditioned reflex of salivary flow can by repetition under appropriate circumstances bring about reflex inhibition, and sleep ensues. Sleep can be produced at any time, infallibly, by conditioned technique. If the internal inhibition is confined to the motor cortex, the clinical condition of the animal is one of catalepsy; it is hypnotised. In the latest adaptation of his laboratory methods Prof. Pavlov's operator is in one room while the animal is in another. All that is requisite is to set the machinery in motion; stimuli, invisible and inaudible to the experimenter, are repeated mechanically; at the end of the experiment he goes into the animal room and there is the dog, fast asleep. Possibly still more remarkable are the results of investigation in regard to what most people would call animal psychology, a term which the Russian physiologist discards as otiose. Studying the whole behaviour of the dog, as expressed in synthesis and analysis, he finds that three general classes or types of animal can be distinguished. In the first, irradiation of excitation takes place with facility and regularity; in a second, irradiation of inhibition is always pronounced; in a third, the two processes are more evenly balanced. The animal of the first group is of a choleric temperament, while the second is melancholic; the third group is divisible into two subgroups, representing the sanguine and phlegmatic temperaments respectively. Is all this somewhat speculative and far-fetched? we may ask with perhaps a little impatience. The answer is that it is possible actually to produce neurotic manifestations in the dogs of the first two classes, and Prof. Pavlov gives us all the details of his method. This consists, briefly, in causing conflict among conditioned stimuli and conditioned reflexes. Take a dog of excitatory type, in which inhibition is always weak; apply two stimuli, one immediately upon the other, differing slightly from each other but so arranged that they collide, as it were; then at once, or after a few repetitions, the dog becomes positively ill. He retains only excitatory processes; the normal relation between excitation and inhibition has disappeared; the animal "breaks down" nervously, and often remains so for months at a time. It is a serious illness, for which treatment is necessary. Similar but opposite circumstances occur in the case of the group with predominance of inhibition. But the normal animal can be experimented with along the same lines without any untoward effect. He must be unimaginative indeed who fails to realise the import of these physiological experiences of the laboratory for the clinical problems of the psychopathologist and neurologist.

◆

SURGERY OF THE CHEST.

The increasing success that is attending surgical operations on the thoracic cavity, so admirably described by Dr. R. A. Young in his masterly review of the subject in the Lumleian lectures, concluded in our present issue, may make us wonder why this branch of surgery has remained so long undeveloped. We may experience still more surprise when we realise that Sir William Macewen, in 1895, removed the whole of one lung for advanced tuberculous disease, and that the patient survived and was alive 18 years afterwards. The reason may well be that the delicately coördinated, highly organised team-work described by Dr. Young is essential to success. Without it sporadic, perhaps fortuitous, successes will occur but steady advance will never be made. The mortality will inevitably remain too high to encourage the physician or general practitioner to call in the aid of the surgeon. The component parts of such a team are these: a physician who is truly expert in chest diseases, with a mind critically receptive of any fertile suggestions for improvement in the technique of treatment; a surgeon who is not only master of a skilful and gentle technique but who can appreciate the medical aspect of the case, who will give painstaking attention to every detail, and is willing to learn by the experience of those who have already trod the thorny path of the pioneer; an anæsthetist who understands the special problems of thoracic surgery; sisters and nurses who are highly trained, observant, sympathetic, and who realise the importance of conscientious and continuous nursing; and an expert assistant. Another essential factor in such a team is that its members should remain associated together for some time and should not be continually changing. Such a team is not so easily formed in this country perhaps as elsewhere, and it may make us wonder whether the newer fashion of frequent changes amongst hospital sisters is so helpful as the older régime, where, though the sister might develop into something of a tyrant, she was certainly a highly skilled person. A physician without imagination, and whose scepticism has been heightened by contact with indifferent surgeons, may effectively hinder progress by refusing to consider surgical treatment. A surgeon and an anæsthetist who fail to learn from the experience of others will do the same. The pioneer work has been done. Experience has been gained at the expense of a high mortality, justified because the conditions were desperate. But there cannot be many little pioneers burgeoning in many parts, all working out their own salvation. Details such as the perfect adhesion of the pleural layers in certain cases of thoracotomy, the temperature of the operating theatre, the decision to operate in one or more stages, the choice of the mode of anæsthesia, will turn the scale between a successful and a fatal issue.

The advance in both diagnosis and treatment of diseases of the chest in the last two decades is remarkable. It is but a few years since Jacobaeus published his paper on thoracoscopy, in which he described a series of cases of innocent intrathoracic tumours, several of which were successfully removed by Einar Key. Not only did his paper stimulate work on this subject, but it raised again the possibility of successfully removing malignant tumours. As Dr. Young points out, there are many difficulties, whether technical or inherent in the morbid anatomy of the chest, but enough has been achieved to enable us to hope that new routes of approach may be discovered, and that tumours may be recognised at an operable stage. Even where removal is not possible, it is to be hoped that a path may be found for the effective application of radium. Dr. Young has compressed into his series of lectures a well-nigh incredible amount of valuable information, enriched by observations from his own mature experience. Their peculiar value is that there is scarcely a word that will meet with dissent from any expert worker on diseases of the chest throughout the world. They will, we trust, be read and inwardly digested by every medical man who has patients under his care. The present unsatisfactory state of the treatment of bronchiectasis is indicated, and yet enough is said to suggest the lines on which ultimate success may be achieved. The lecturer's summary of the treatment of empyema is admirable; from the oceans of literature on the subject Dr. Young has succeeded in extracting the pearls. Such knowledge still needs wide dissemination. Many of the accepted beliefs in the profession at large on the subject of empyema are hazy and erroneous. How many know exactly when an empyema should be tapped, when a rib should be resected, and when not? In pulmonary tuberculosis, how many practitioners are able to discern when a case is passing beyond the aid of ordinary measures, and when so passing what is the right course to adopt? The review given in the Lumleian lectures cannot fail to increase the knowledge of what may be achieved by thoracic surgery and materially to assist in its evolution.

◆

THE SAVING OF THE CRIPPLE.

In no phase, perhaps, of preventive medicine has progress been so rapid and effective as in the treatment and cure of crippling in children. The story of the recent change in the public attitude towards the cripple from one of fear and repugnance, existing from earliest times when the deformed were persecuted as possessed of the devil, through a period of grudging tolerance of suffering and deformity as a necessary evil, to the modern standpoint that most of the crippling can be avoided, is told by Sir Henry Gauvain and Dr. Evelyn Holmes in a paper whose publication we conclude this week. This change of attitude has been brought about by the devoted services of a few lay and medical pioneers, including Mrs. Humphry Ward, Mrs. C. W. Kimmins, Sir William Treloar, Sir Henry Gauvain, and Sir Robert Jones. The lay workers established schools where the personality and character of the sufferer was allowed to develop along normal lines in a somewhat sheltered communal environment, while the medical men proved how unsatisfactory was the so-called radical treatment in comparison with the conservative methods now relied on to prevent the disastrous consequences of crippling diseases.

Official recognition of the special needs of crippled children has but slowly followed in the trail of these leaders; perhaps necessarily so, since no public body dare spend money until public opinion is assured that expenditure is justified. Now, however, the lag of indifference and laissez-faire is being overtaken. The best aspects of sporadic, voluntary, and official methods are being coördinated to deal with this mass of needless suffering; schemes for orthopædic treatment, embracing the work of private practitioners, medical officers, consultants, and voluntary bodies are springing up all over the country, and new methods and a broader national outlook are moulding and forming a policy which promises to prevent, as Sir Henry Gauvain and Dr. Holmes estimate, between 70 and 90 per cent. of the amount of disability now occurring. Certainly the elementary school child has the promise of greater and ever greater facilities for effective medical supervision, prevention, and treatment, but Sir Henry does well to draw attention to the needs of children of the secondary and public school classes in our nascent schemes for dealing with crippling. There are at present no means whereby crippled children from well-to-do homes—even with considerable outlay—can benefit by prolonged hospital school treatment, comparable with that available for the State-aided child. True, some 70 per cent. of crippling is found among the poorer strata of society, but this still leaves 30 per cent. among the other classes who cannot have prolonged treatment of the right sort. The average length of stay in hospital schools to ensure quiescence and stabilisation is perhaps two years, during which time not only specialised medical treatment but education along the right lines is essential. This period of more or less active therapy is properly followed by daily attendance at special physically defective schools where effective medical and nursing supervision is continued, if necessary until the child is 16 years of age, whilst his later progress may also need to be watched in special cases. No such facilities, however, exist for other than State-aided children. We know that untreated physical defects by excluding children from the corporate life of their fellows often lead to a sense of inferiority and to social inefficiency, and Sir Henry Gauvain and Dr. Holmes are right in expecting the support of the medical profession when they say that we have here a state of affairs that must be remedied.

In his wise conception of the needs of the body Sir Henry has from the first appreciated the necessity of tending the mind by suitable education, not alone to supply the immediate requirements of interest and happiness that help to maintain or restore health, but also to supply knowledge, and the means and ways of applying knowledge and of adaptation when the child later takes his place in the industrial world. In acute illness rest is essential, both of body and mind, and the question of occupying the mind does not enter into the scheme of general hospital treatment. But during convalescence from acute illness, such as rheumatic fever, or in the long periods required in treating the cripple, a cheerfully occupied mind is of the first importance. All convalescent and other hospitals taking patients of this kind should therefore have educational facilities as a fundamental part of their equipment, the educational side being part of the medical treatment and under the direct supervision of the medical man. Sir Henry says that nearly 1 per cent. of all elementary school-children need treatment and special education for crippling defects—i.e., between 30,000 and 60,000—and if we add some 10,000 children not of the elementary school type we get an idea of what has to be done. The age of onset of crippling, other than that of the heart, falls predominantly in the pre-school era, and there are indeed many who believe that the seeds of rheumatic heart disease are also sown before school age. Over and above this the school medical service has shown that some 30 to 40 per cent. of school entrants suffer from minor defects. All this clearly indicates how great is the need for an effective medical supervision of the pre-school child, and it is not unlikely that the next big step forward in preventive medicine so far as the poorer classes are concerned will be an extension of maternity and child welfare schemes to embrace all children from conception to the school age. The growing momentum of combined social and medical preventive work must be clearly recognised, but the task of resolving these forces along satisfactory lines is not one that can be attempted by anything less than a united professional opinion.

Pathological Research in its Relation to Medicine.—A course of lectures on this subject will be given at the Institute of Pathology and Research, St. Mary's Hospital, London, W., on Thursday afternoons, at 5 P.M., from April 25th to June 13th inclusive. The lecturers will be Sir Almroth Wright, F.R.S., on the Experimental Method in Medicine (April 25th); Prof. Ariens Kappers, of Amsterdam, on the Phylogenetic Development of the Protopathic and Epicritic Centres in the Central Nervous System (May 2nd); Dr. E. D. Adrian, F.R.S., on the Nervous Mechanism of Sensation and Movement (May 9th); Prof. F. T. G. Hobday on the Value of Research into Animal Diseases as an Aid to the Study of the Diseases of Man (May 16th); Prof. W. W. C. Topley on the Natural Acquirement of Immunity (May 23rd); Prof. F. W. Twort, F.R.S., on the Position of Ultra-microscopic Viruses in the Living World (May 30th); Prof. William Bulloch, F.R.S., on the History of Bacteriology (June 6th); and Prof. J. A. Gunn on Variations in Susceptibility to Drugs and Toxins (June 13th). These lectures are open to all members of the medical profession and to all students in medical schools without fee.

Annotations.

"Ne quid nimis."

THE KING.

WE published in THE LANCET of April 6th the official bulletin issued from Craigweil House on March 29th. Another bulletin was issued from the same residence on Sunday, April 14th, as follows: "His Majesty the King continues to make satisfactory progress, and the rheumatism of the right shoulder is yielding to treatment." The bulletin was signed by Sir Stanley Hewett and Lord Dawson of Penn.

THE LOCAL GOVERNMENT ACT.

As a forerunner of the detailed memoranda to be issued to local authorities on the different parts of the new Local Government Act, the Minister of Health has promulgated a general introductory circular, from which extracts are printed on p. 841 of this issue. The circular summarises with remarkable lucidity the principles of the new law; it sets out the defects of our present system, and it names the remedies which the Act provides. It explains the transfer of the functions of poor-law authorities to the councils of counties and county boroughs, the readjustment of the cost of roads, the proposed survey of the areas of county districts, the derating arrangements, and the distribution of consolidated grants according to the needs of the areas concerned. While drawing attention to the actual administrative and financial changes in prospect, the Minister takes this early opportunity of emphasising the importance of the spirit in which the Act is operated; he asks for the fullest collaboration from local authorities, their officers, and the general public in the task of developing a scheme of sound local government, and particularly the protection and improvement of the health of the people. The Local Government Bill, which received the Royal Assent before the Easter adjournment, had a fairly smooth passage through Parliament. Based on past recommendations to which members of all parties had committed themselves, advocated in the House of Commons with masterly skill and team-work, its principles were but little shaken by political opponents. But there are still difficult days ahead. Duties cannot be taken from hands which have discharged them with pride and fidelity, nor can the traditional boundaries of the English countryside be altered, without umbrage and irritation. There is no need to take notice of the facile and unworthy criticism of those who, themselves shirking the necessary study, protested that the proposals were too complicated to be commended to modern democracy. The Act is now upon the statute book, and the citizens to whom its administration will be confided can examine it before its main provisions take effect in April next year. Evidently the Ministry will give all possible assistance, though at this point two observations may perhaps be permitted. The first is that departmental memoranda are not a complete substitute for the actual text of the statute; even if the week-end of Easter intervened, it is disappointing that an important Act of Parliament passed on March 27th should be still unpublished more than a fortnight later. The second is that the Minister can earn the gratitude of all medical officers of health and members of local authorities if he will set the official draftsmen (who will have unusual leisure in the next few months) to work on the re-statement of our local government enactments in an orderly code. The consolidation of those enactments involves neither political controversy nor a charge on the public purse. They were notoriously in a tangle before; their state is far worse now.

GLAUCOMA SECONDARY TO IRITIS.

CASES of iritis or irido-cyclitis which develop high tension are among the most difficult that the practitioner has to encounter. On the one hand, an eye with raised tension is glaucomatous, and the first thing to be done in cases of glaucoma is to instil eserine. On the other hand, the remedy for iritis is atropine, and eserine is distinctly harmful. What, then, should be done? At a discussion on the causes and treatment of irido-cyclitis with raised tension at the 1928 Congress of the Ophthalmological Society (the report[1] of which appears in advance of the present Congress) three types of cases were distinguished by Mr. W. H. McMullen. In the first type increase of tension occurs soon after the onset of acute inflammation. In these cases there are usually abundant keratic precipitates and the anterior chamber is usually deep, or at any rate not shallow as in primary acute glaucoma. Some authorities have advocated the use of miotics in these cases, but the weight of opinion is decidedly against them and in favour of pushing atropine as in ordinary cases of acute iritis. Atropine keeps both iris and ciliary muscle at rest and it prevents the formation of synechiæ. To combat the inflammation is the best means of preventing the increase of tension due to it. If, however, the tension does not come down, and especially in cases where the anterior chamber is shallow, the difficulties of deciding on the line of treatment are great. In proportion as the case approaches in character to one of primary glaucoma the temptation to use eserine becomes strong. Mr. Harrison Butler, while advocating the pushing of atropine in these cases—the higher the tension the more he would push it—admitted that in some cases this would not do. In some doubtful cases he used homatropin alternating with pilocarpine, by which method he avoided adhesions and yet prevented the iris from bunching up in the angle of the anterior chamber, mechanically raising the tension. The question of operation was discussed but it was generally agreed that with acute irido-cyclitis it should, if possible, be avoided. Iridectomy, involving trauma of a structure in a state of acute inflammation, is obviously contraindicated. Trephining is liable to be followed by blocking of the trephine hole by exudation. The simplest procedure is the best, but tapping the anterior chamber by paracentesis has only a very temporary effect and it may not be feasible to repeat it many times. Some form of sclerotomy is probably the safest procedure in case of necessity, and some surgeons speak well of Herbert's "small flap sclerotomy." It is impossible to lay down any general rule for these cases, each of which must be judged on its own merits. For the general practitioner the chief moral is the necessity of being able to distinguish between primary and secondary glaucoma, so as to make no mistake in taking the emergency measures called for when a specialist cannot at once be consulted.

Mr. McMullen's second type of cases comprises those resembling acute or subacute glaucoma in which careful examination reveals signs of uveal inflammation. These differ from the first type in that the signs of iritis or cyclitis are not nearly so obvious or so severe. The keratic precipitates may be so slight that they can only be detected by the slit-lamp. In these cases, to quote Mr. McMullen, "it is probable that the irido-cyclitis is not the essential factor but that we have to deal with eyes that were predisposed to glaucoma by anatomical or other changes, eyes in which the mechanism for regulation of pressure allowed a very small margin of safety, and that the occurrence of a slight irido-cyclitis upset the delicate balance and determined the onset of glaucoma." Indeed, these cases approximate to true glaucoma, and before the general use of the slit-lamp and corneal microscope passed as such. It has even been asserted that most cases of so-called primary glaucoma are really of this type, but here there is the possibility of a fallacy. According to Mr. Harrison Butler, in the case of pigmentary deposits on the back of the cornea so minute that they can only be seen with the slit-lamp, these are not necessarily the results of an inflammatory process, for in elderly people the pigment round the pupil margin tends to become free as the result of a senile degenerative process and being deposited on Descemet's membrane may simulate true "K.P." In his opinion the majority of doubtful cases turn out to be primary glaucoma. In general we may say that the objections to treating this second type of cases as true glaucoma are much less valid, and operation is generally called for, either iridectomy or sclerectomy.

---

[1] Transactions, vol. xlviii., pp. 45–82.

Cases of the third of Mr. McMullen's types are those of chronic irido-cyclitis in which increase of intra-ocular pressure occurs months or years after the onset of obvious inflammation. When it is long continued nothing but operation is likely to relieve it permanently. In the absence of an acute attack iridectomy may have a favourable affect on the irido-cyclitis, and this combined with some procedure which will result in a filtering cicatrix is generally indicated. In chronic or subacute cases where there is time to investigate the possible causes underlying the condition and especially any form of septic infection, the effective removal of such causes must naturally take precedence over other treatment.

LEPROSY IN AUSTRALIA.

A NOTEWORTHY contribution to the epidemiology of leprosy has been made by Dr. Cecil Cook,[1] Wandsworth Research Scholar of the London School of Tropical Medicine, and appears opportunely at the opening of a campaign for the elimination of leprosy from the British Empire within a generation. To quote the prefatory words of Dr. J. H. L. Cumpston, Director-General of Health: "This volume presents for the first time a complete record of the known facts relating to leprosy in Australia."

Among the many problems confronting Dr. Cook was the variable behaviour of the disease in different parts of the continent. For example, why does leprosy attack the white population of New South Wales and not that of Victoria? Why does the legislation, which is effective in controlling the disease in New South Wales, fail to prevent an actual increase in prevalence in Queensland? Again, the difficulty in tracing case-to-case infection led Ashburton Thompson to the conclusion that in New South Wales the evidence pointed to the probability "that the infection of leprosy is received by man from his environment rather than from the sick." Dr. Cook carried out his investigations during the years 1923–25 and, for the purpose of studying local conditions in endemic areas, examining relatives of patients and making a leprosy survey of territory hitherto overlooked, he travelled about 15,000 miles by motor, several thousand miles by rail and steamer, and some hundreds on horseback. He deals in separate chapters with leprosy in the Northern Territory, Western Australia, Queensland, New South Wales, and Victoria. His account of the origin of outbreaks of leprosy will be convincing to most of his readers. There was no leprosy, he says, amongst the aborigines before the white settlement of the continent, but the disease was not introduced by the whites. During the gold-rushes of the sixth decade of the nineteenth century there was a large influx of Chinese labourers, and about a decade later of Polynesians, and amongst the immigrants of both races there were many lepers. These immigrants consorted with the aboriginal women and the tribes of aborigines in due course became infected. In the early days each tribe kept to itself but the gradual removal of intertribal restrictions facilitated the spread of infection. The pioneer white population were males only and a decade or two later the disease spread to them owing to cohabitation with infected aborigines. There was no sufficiently intimate contact between the infected aliens and the whites to provide for direct transmission of infection. The aboriginal women filled the rôle of intermediary; the whites were infected a decade or two later than the aborigines and the first whites infected were adult males. When the pioneer white communities were replaced by families, the white infection became domesticated, as in New South Wales. The early disappearance of the aborigines from Victoria to the northern regions removed the intermediary link but the original method of infection is still operative in the north. The increasing prevalence in Queensland is, he considers, attributable to unrecorded cases, unsuspected undiagnosed cases, and concealed cases. In the early days the medical men were unfamiliar with the disease and it has often been regarded as syphilis.

In the course of his report Dr. Cook goes fully into the possible ways in which the disease is spread. Hereditary infection he regards as untenable, although the history of certain families cited may suggest the transmission of a predisposition. Environment per se is powerless but if human infection is introduced it seems to spread more easily in humid coastal regions than in dry inland areas. Moreover, the form of the disease prevalent among the whites —though not the aborigines—in the dry inland districts is the neural non-infective type. Dr. Cook's investigations do not lead him to attach importance to the effect of biting insects or to the possibility of true insect vectors. The bed-bug is absolved. While admitting that there is a prima facie case for the transmission of leprosy to man from the rat by the agency of *Xenopsylla cheopis*, he points out that the conditions of life among the aborigines do not favour this means of transmission. He sums up Australian experience by saying that "where infection has not been domestic, the commonest indication is infection from aborigines under circumstances provoking contact of the most intimate nature—cohabitation and sexual promiscuity." He draws the conclusion that leprosy "should be readily eradicated by a system of prophylaxis which ensures that lepers shall have no opportunity of associating closely with uninfected persons," and goes on to emphasise the weak points in the present system, including the lack of inter-State coöperation.

THE COMMON COLD AND ULTRA-VIOLET LIGHT.

THE sufferer from frequent heavy colds is a miserable creature. He gets little sympathy from friends whose experience of colds amounts to no more than a couple of days' discomfort; his employer will allow no sick leave for a "mere cold"; his relatives shun him for fear of infection; his doctor has nothing to suggest save time-honoured palliatives that scarcely palliate; and his Minister of Health execrates him for going about the world spreading germs. Meanwhile he is struggling to carry on while feeling really ill for about a week, and he is likely to be "run down" for the best part of a month afterwards. The cold is a difficult thing to study statistically, but a college group offers a good field for investigation, and the department of hygiene at Cornell University has realised the possibility of reducing the catarrhal chaos to some kind of order by observing the students in residence. Dr. D. F. Smiley,[1] who records some of his findings among 2485 students of both sexes, says that there seemed to be a definite group of people (rather less than 20 per cent.) immune to colds, and another group (rather more than 20 per cent.) seriously susceptible in that they had four or more every year. A graph shows that it is the small susceptible group who are really responsible for the winter epidemics, and Dr. Smiley believes that any measure which would control the colds of the few who have more than four a year might very well eradicate the big epidemics which cause so much loss of time and endanger so many lives. He was unable to find any difference in the general physique or physical make-up to distinguish the cold-susceptibles, but their history showed a greater liability to asthma, hay fever, and infectious disease. Smoking, mouth-breathing, sleep- and exercise- habits, clothing, exposure to draughts, tendency to perspiration, family history, and the use of a daily cold bath, could—according to the Cornell figures—all be discounted as ætiological factors in the "cold diathesis." There was, therefore, nothing to guide prophylaxis. Previous experiments had convinced Dr. Smiley and Dr. G. H. Maughan that there was a definite reciprocal relationship between the incidence of acute respiratory infections and the average daily hours of sunshine, and it occurred to them that there might be some vitamin deficiency or disorder of vitamin metabolism during the dark months of the year which would lower the resistance of the human body to cold-producing organisms. On this hypothesis 23 of the sensitive Cornell students were irradiated weekly with a quartz mercury-vapour lamp, a control group receiving no treatment. The dosage was small, as the investigators thought it had been excessive in previous experiments where results had been negative. The average number of colds for the autumn term was 1·56 for the irradiated students and 2·80 for the untreated, the figures being 1·24 and 2·79 respectively in the second term. Smiley and Maughan are conservative in their claims, but suggest that their results justify the use of short weekly irradiations with ultra-violet light in cases of marked susceptibility to colds where even a 40 per cent. decrease in incidence would be welcome. Much larger series will be required to convince the sceptic, but this contribution may be regarded as supporting the people who believe that they are saved from winters of misery by systematic irradiation or by immediate exposure for a few minutes as soon as the premonitory symptoms of the dreaded cold are experienced.

THE CENTENARY OF BILLROTH.

LAST week the profession in Germany and Austria celebrated the centenary of one of the outstanding personalities in the medical history of the nineteenth century.[1] Theodor Billroth was born on April 26th, 1829. He was a great surgeon, perhaps the greatest of his time, but what distinguished him more than any one attainment or quality was his possession in equal measure of those gifts which capture the heart and imagination. Besides his surgery he had an exhaustive experimental knowledge of anatomy and histology; his work on wound infections made him a pioneer of bacteriology; he was a good musician and composer, and he enjoyed 40 years of successful married life. A man of robust figure and dominant personality, strikingly expressed in his flowing beard and piercing eyes and in the voluminous cloak and broad-brimmed hat which he habitually wore, he was a source of inspiration to hundreds of colleagues and students and to thousands of patients. He was a pioneer in many more ways than in research. He decisively rejected the forbidding bedside manner which too many of his countrymen regarded as an indispensable professional adjunct, and devoted himself to encouraging his patients before their operations and putting forth every effort to restore them afterwards to the best possible state of mind and body. His relations with his patients gave him an almost superhuman reputation, and sufferers used to drag themselves hundreds of miles to his clinic in the hope that he would cure them when every other surgeon had given them up. Their attitude was expressed in the pathetic exclamation of a mortally wounded Prussian officer when Billroth walked into the ward: "Thank God! Now I'm saved." One of his greatest services to German surgery was his instant acclamation of Lister's discovery. He sent his assistant to Edinburgh to learn the new methods at first hand, and introduced them with relentless firmness into his hospitals. He was a great writer and a great teacher, and held many famous chairs, but in 1867 he went to Vienna, which so enthralled him that even the offer of his old master Langenbeck's place could not tempt him back to Berlin. A witty contemporary said: "Austria could not have taken a finer revenge for Sadowa than to annex the best thing Prussia possessed." In spite of a critical attack of pneumonia in 1887 he lived to celebrate his twenty-fifth year as professor of surgery in Vienna, but shortly afterwards it became obvious that his heart was failing. Strength of will enabled him to remain in harness almost to the end, but towards the end of 1893 he had to retire to the Albazia, the hospital for which he had such a strong affection and which he had practically made his own, and in February of 1894 he died. The enthusiasm with which his centenary is being celebrated testifies to the universal admiration which he inspired. His unique value lay not so much in what he did as what he was.

THE REPORT ON RADIUM.

ON March 25th, as was reported in THE LANCET at the time, Lieut.-Commander Kenworthy asked the Minister of Health whether he had received the report of the Subcommittee of the Committee of Civil Research on radium and radium supplies; and whether it was proposed to publish it in whole or in part. Sir Kingsley Wood replied: "The report has been received and will be published in full very shortly. I may add that a statement of the intentions of the Government in the matter will be made immediately on the reassembling of Parliament." It is an open secret that this announcement was received with mixed feelings by members of the medical profession, who cannot have expected that the intentions of the Government would be formulated as a result of a report the contents of which was a complete secret to them until this week, while the personnel of the authors of the report had not been made really public. Undoubtedly the presumption was that the report, in the composition of which no representatives of clinical medicine appear to have been consulted, would be submitted for deliberation, at any rate, to a duly selected list of professional leaders before Parliament was invited to act upon it, for action must be taken to follow upon intention. On Tuesday last, however, the announcement was made by the Chancellor of the Exchequer that the Government had decided to contribute £1 for £1 raised by public effort to obtain a sum of £200,000 to be expended in the purchase of radium, the employment of which, presumably will follow the lines of the report of the Subcommittee, and on Wednesday the report became available for the public. Before the public is asked to assist in the raising of a purchase fund, there ought of course to be no question as to whether the members of the medical profession, as trustees for the proper therapeutic uses of radium, are properly satisfied as to the husbanding and allocation of the supply of radium, when obtained.

A summary of the report is published in another column, and it will be seen that the Subcommittee have covered the ground very thoroughly. The growing importance of radium as a therapeutic agent is clearly explained, and the fact emerges that since systematic studies of a comprehensive character have been undertaken in regard to the biological and curative properties of radium, the possibilities of radium surgery have been recognised to the great benefit of the world. Hence the need for obtaining a stock of radium is pressing, while an analysis of the existing supply for medical treatment in this country shows a very definite shortage. The amount of radium at present required for medical purposes in England, Scotland and Wales is calculated as being 49 g., of which it would seem 24 g. only are in our possession. The basic recommendation of the

---

[1] Wien. klin. Woch., April 11th, p. 457.

Subcommittee is that there should be a definite aim at securing a net increase of 20 g. of radium to be available for medical purposes by the end of 1930. The market to which recourse must be had is Belgium, for the figures show that at the present time very little radium is being produced anywhere except from the Belgium Congo ore, and it is possible that the privacy in which the activities of the Subcommittee have been transacted was due to the feeling that it was important that no public surmise should influence the prices. Clearly our holding must be increased, and the proposed organisation for the distribution of a central stock of radium for medical purposes turns upon the constitution of a body of Trustees whose duty it will be to hold the funds provided by Parliament or otherwise, and to purchase therewith and hold radium for use by an expert body termed the Radium Commission; and at this point the claims of clinical medicine to be recognised are met. The National Radium Trustees include the Presidents of the two Royal Colleges, the B.M.A., and the Royal Society of Medicine, while the Radium Commission, a body of nine, will consist of four persons nominated by the Trustees, and four representatives nominated, one each by the Minister of Health, the Secretary of State for Scotland, the Medical Research Council, and the Department of Scientific and Industrial Research, with a chairman, "a distinguished public man," who, however, will not necessarily be a member of the medical profession.

Of the report of the Subcommittee there can be but one opinion—it is a clear document, packed with facts which support its recommendations. But the omission to take the medical profession into consultation before the report was made must by the members of that profession be regarded as a possible source of weakness in the future.

THE BALANCE OF POPULATION.

THE excess of live births over deaths in England and Wales during the year 1927 was only 169,503, a figure 60,000 or more below that of the three previous years. The Registrar-General, who notes this curious fact in the third part of the Statistical Review of the year which has just appeared,[1] explains the excessive drop in the natural increase of population by the conjunction of a special decrease in births and an equally fortuitous increase in deaths. The former was due largely to the abnormal decline in the number of new marriages in 1926, associated with the prolonged coal strike and the industrial disturbance of that year. The mortality of the year was not high in itself but was merely relatively so in contrast to the low record of 1926. Every cause set out in the table of causes of death shows a higher mortality for each sex in 1927 than in 1926, with the single exception of the category Old Age, a form of return which has been rapidly declining in frequency of recent years. This growing reluctance to attribute death to old age must help in some degree to account for the increase from more definite causes. Taking the various causes of death seriatim the greatest increase of 1927 as compared with 1926 is from influenza, heart disease and cancer coming next; but when comparison is made with 1921–25 the increase from influenza is naturally less outstanding, heart disease ranking first and next to it cancer. Both these rates are likely to be swollen by transfer from Old Age; heart disease as a result of the increasing record of myocardial disease on the certificates of aged persons, and cancer as a result of the increasing frequency of the disease in the old. As the Registrar-General points out, the population as a whole is gradually getting older and will continue to do so for many years to come owing to the heavy falls which have occurred in both fertility and mortality during the past half century. We must not infer, he says, that the perpetuation of current conditions of fertility and mortality will be sufficient to ensure a continuous increase in the national population.

TWO GIFTS TO LONDON CHILDREN.

DURING the past week London children have benefited by two generous and imaginative benefactions. Sir James Barrie has given all his rights in "Peter Pan" to the Hospital for Sick Children in Great Ormond-street, and it is estimated that the gift, which is wholly unconditional, will produce an income of something like £2000 a year. This generous action has already borne fruit, for "The First Pirate" has anonymously given a pound note in the hope that others may follow his example. The second benefaction is the offer by Lord Rothermere of £100,000 towards the purchase of the Foundling Hospital site, the option on which is to be kept open until June 30th, 1931, Lord Rothermere having made himself responsible for the annual interest on the remainder of the purchase money in the meantime. The fact that the Foundling site lies so near to the Children's Hospital made the proposal (now abandoned) to rebuild the hospital on this site seem a natural one, although it is perhaps still more fitting that the area should be kept open in perpetuity as a children's park, in accordance with the conditions laid down by Lord Rothermere, who has stipulated in addition that the park shall be placed for one month in each year at the disposal of the British Boy Scouts Association for a camping ground. Sir James Barrie's benefaction recalls a similar act of beneficence on the part of a great artist, for Handel left the score of "The Messiah" by will to the Foundling Hospital, and during his lifetime a sum of more than £10,000 was added to its funds by the annual performance of the Oratorio within the hospital on the great organ which he gave to it. The Foundling site will provide a large open space in a part of the metropolis which has stood greatly in need of one ever since Lamb's Conduit Fields were built over, after the governors of the Foundling Hospital had bought 55 acres of these fields from the Earl of Salisbury for a matter of £5500. The little green patches provided by squares and churchyards in the middle east of London, even if they were available for children's play, do not take the place of the wide areas of wilderness in the western districts, and those who are familiar with the way in which Clissold Park, a mile or two further north, is used by the dwellers in the further east who trek there and back on fine, summer afternoons, can form some conception of what the Foundling site when it is laid out will mean to the children of Agartown and Somerstown. If there is not room for ornamental water there will at least be playing fields and sandpits and possibly some small enclosures where bright-coloured fowl and cavies can rejoice the heart of the urban child.

INTERNATIONAL SURGICAL CONGRESS.

THE Eighth Triennial Congress of the International Society of Surgery will be held in Warsaw from July 22nd to 25th, when the following subjects will be discussed: The Causes and Mechanism of Post-operative Embolism; the Results of Resection of the Stomach for Gastric and Duodenal Ulcer; the Treatment of Exophthalmic Goitre and the Reparative Surgery of the Hip-joint. The Society has chartered a liner of the Compagnie Générale Transatlantique for the use of members; this will leave Zeebrugge on July 12th and after calling at Ymuiden, Copenhagen, Riga, Helsingfors, Stockholm, and the Island of Gothland will arrived at Danzig on July 21st. From here Warsaw is only eight hours by rail. Messrs. Thomas Cook and Son are arranging inclusive terms for the stay in Warsaw and for the journey from London for those members who do not wish to join the preliminary cruise, with an extension to Vienna, Budapest, Prague, and Leipzig after the Congress for those who desire it. As the hotel accommodation in Warsaw is understood to be limited early booking is desirable. The British delegate is Mr. J. E. H. Roberts (26, Harley-street, London, W. 1), to whom intending participants are invited to refer.

[1] The Registrar-General's Statistical Review of England and Wales for the Year 1927. Text. H.M. Stationery Office. 1929. 5s.

THE RETURN OF SEVERE SMALL-POX.

The disembarkation from a British ship at Marseilles on March 27th of a seaman fatally ill with small-pox, and the distribution over this country of nearly 1500 possible contacts, has set the public mind again thinking of small-pox as a dangerous disease. For many months past 200–300 cases of small-pox have been notified each week from widely scattered counties in England and Wales, but only an occasional fatality has been reported, with some other contributing cause of death appearing as a rule on the death certificate. The small outbreak of 11 cases of small-pox in London two years ago, which led to six deaths, was attributed to some undisclosed case imported from abroad; and a little earlier the married couple who sickened of small-pox in its hæmorrhagic form had recently arrived from Paris. In neither of these instances was there any extension of the severe disease to the population at large, but the danger of the present situation has been accentuated by the fact that the seaman landed at Marseilles had been ill on board for ten days before the disease was recognised as small-pox, and about one-third of the passengers left the boat at Marseilles to cross France for England before any precautions had been taken to protect them from the results of possible contact. From the details given on another page it will be seen that, in spite of the extraordinary favourable opportunity offered for the development of widespread infection in a closed community on shipboard, only 42 secondary cases of small-pox have occurred, with a total to date of six deaths. All persons on board the vessel were offered vaccination or revaccination between Marseilles and Liverpool where the passengers disembarked, the crew proceeding to dock with the ship at Glasgow. At these ports the health authorities decided that the situation would be fully met by keeping them under observation during the critical period, and by the usual careful surveillance of contacts, a policy which seems to have been justified by the event. On the other hand, the health authorities in France, which relies for protection against small-pox on the principle of universal compulsory vaccination, threatened to apply this policy logically by refusing (from Thursday of this week) to admit into the country any passenger from England who was not prepared with evidence of recent vaccination. Opportunities were to be offered both on the crossing and on arrival at a French port for the traveller to comply with this regulation, while the tourist companies were to make arrangements for such through passengers as desired to avoid the regulation by travelling on the eastern side of the frontier. At the last moment the order was suspended. Recent vaccination, however, would ensure the safety of the traveller in France as well as the converse. The present position affords an interesting commentary on the need for complete international agreement as to the methods to be adopted for dealing with small-pox when, as must happen from time to time, it again presents itself in a dangerous form.

THE MICROSCOPE ON SHIPBOARD.

Dr. R. Pirot, a French surgeon lieutenant-commander, serving in China on board a gunboat of 800 tons and 110 men, tells [1] of the medical advantage he gained during his cruise from taking a microscope with him and fitting up a small laboratory on board. The diagnosis of malaria without a blood-film examination is, he truly says, impossible; clinically, the disease is often missed or identified wrongly. Again, everyone is now so anxious about venereal prophylaxis that treatment is sometimes over-active and Pirot found himself able, by examining pus-films, to decide that some chronic discharges were due to a chemical, not to a venereal, urethritis, and so to get them stopped. In other such cases, by definite recognition of the cause of very early infective discharges, he was able to start vigorous treatment at once, which without a microscope he would not have dared to do. But it was in the study of intestinal parasites he found his little laboratory most useful, as there were some 20 natives on board, of whom a third were infected with *Necator americanus*, and others with other intestinal parasites; in fact, he did 200 examinations of fæces in the year. Thus, also, he could diagnose amœbic dysentery early and begin emetine treatment forthwith, with great advantage to the patients. Altogether he did 377 examinations in the year, and wishes all to know that such a laboratory is possible even on board a small craft. Like Molière, he took his good where he could find it, wiling acetone out of the gunner, and wire (mirabile dictu) out of the wireless operator; but most of his stains came from a kindly Pasteur Institute. He is rather proud of a useful centrifuge he made out of a ventilating fan, but in his small (10 ft. by 10 ft.) laboratory, and in those climates, he must have sometimes regretted that the centrifuge was not still an electric fan. His only serious difficulty seems to have been that the ship's distilled water was not quite good enough for washing Giemsa and Romanowsky films; so, after watery eosin he stained his films with Stévenel's blue (75 c.cm. of 2 per cent. methylene-blue, and 50 c.cm. of 3 per cent. permanganate of potassium, heated together in a water-bath till the precipitate dissolved). This solution, he says, is permanent; the film need only be washed with ordinary water and gives complete differentiation to the leucocytes.

Summer Time will commence in Great Britain, Ireland, the Channel Islands, and the Isle of Man on Sunday morning next, April 21st, at 2 A.M., when the hands of timepieces should be advanced one hour. It will end on Sunday, Oct. 6th. France makes the change at the same week-end, after which travellers need not alter their watches on crossing the eastern frontier.

During the Annual Meeting of the British Medical Association in Manchester an exhibition of works of art belonging to members of the profession will be held. Medical men are earnestly invited to loan pictures and works of art, and communications in respect of the exhibition should be addressed to the chairman of the Local Entertainments Committee, 33, Cross-street, Manchester.

Royal Medical Benevolent Fund.—During the first quarter of this year £2774 has been voted in grants and £1320 paid to annuitants, these figures showing an increase on the corresponding period of last year. At the recent meeting of the committee 33 grants were made, amounting to £715. The following are short notes on four of the cases helped:—

M.D., aged 76. Sight damaged by X rays in early days of long exposures. Vision of the right eye practically gone and left eye failing. Applicant was one of the earliest workers with radiology in this country. Private income £22. Freemasons have given a pension of £64, making a total income of £86. Voted £40.

M.B., aged 72. For many years has suffered from mitral disease and during the last few months has had increasing difficulty in walking and is unable to work. His savings are being exhausted. Voted £40.

Widow, aged 62, of L.R.C.S., whose husband was a ship's surgeon until his death in February. The widow has been left with no income. Her daughter is earning £130 a year and relations contribute £50, making £180 for two persons. Fund voted £36.

Daughter, aged 61, of M.R.C.S. Her father died when applicant was a child. She was trained as a nurse and supported herself through life as nurse-matron in schools. In 1928 she had a severe operation and has had to give up work. Income, £75. Rent, £26. Fund voted £26.

Subscriptions and donations should be sent to the honorary treasurer of the Fund, at 11, Chandos-street, London, W. 1.

The Clinical Interpretation of Aids to Diagnosis.

A Series of Special Articles contributed by Invitation.

XXVIII.

THE SIGNIFICANCE OF ORGANISMS IN THE URINE.

PART II.*—IDENTIFICATION OF THE ORGANISM.

THE routine laboratory examination of a specimen of urine involves the making of stained and unstained preparations from the centrifugalised deposit, the making of cultures, and, in special circumstances, the inoculation of an animal.

Technique.

At least 10 c.cm. of the specimen is centrifugalised and the deposit used for microscopic examination. An unstained preparation serves for the identification of *pus, epithelium, red cells, casts, crystals, ova, and* motile bacteria. For stained preparations the most satisfactory techniques for routine use are Gram's and Ziehl-Neelsen's methods. In special circumstances dark-ground illumination may be used to search for the leptospira of infective jaundice; alternatively a dried preparation may be stained by Giemsa's method. For cultivation, as a routine medium a simple litmus-lactose agar gives the most useful results in that it helps to differentiate typhoidal organisms from ordinary *B. coli*. Non-lactose fermenting coliform organisms should be identified by subculturing into suitable sugar media and, if necessary, by agglutination. A serum-agar or blood-agar medium should be used where streptococci are to be cultivated. As a routine, the cultures are incubated for 24–48 hours, but in special circumstances, such as examinations for the Brucella group (melitensis, &c.) incubation should proceed for seven days before the culture is regarded as negative.

Animal Inoculation.

Guinea-pig inoculation is performed for the detection of *B. tuberculosis* when, as is frequent, the organisms are too few in number to be detected in a Ziehl-Neelsen stained film. Provided that the specimen does not contain large numbers of pyogenic bacteria the animal is inoculated direct with about 1 c.cm. of the centrifugalised deposit. When pyogenic infection is heavy, the deposit is first treated with an equal volume of 3 per cent. caustic soda for half an hour at 37° C.; at the end of this time it is made neutral to litmus, centrifugalised, and the deposit inoculated. The caustic soda kills off pyogenic bacteria but has little or no action on tubercle bacilli (Petroff's method).

Inoculations are made in the lower part of the anterior abdominal wall, and evidence of tuberculous infection is first given by enlargement of the inguinal glands. Inoculated animals are examined from week to week for loss of weight and for glandular enlargement, and if the glands become easily palpable an autopsy may be performed without further delay. If there is no sign of glandular enlargement, the animal is allowed to live for two months before an autopsy is performed. Any tuberculous lesions are examined in smears, and if necessary, in sections, for evidence of tuberculosis; a positive result is presumptive evidence that the original specimen contained tubercle bacilli. In the average case a definite result from animal inoculation takes from 6–8 weeks to obtain. A guinea-pig may also be used to demonstrate the *Leptospira icterohæmorrhagiæ* in the urine in the later stages of infective jaundice.

B. Coli.

B. coli pyelitis is common in women and children but is not so frequent in adult males; the finding of *B. coli* in the male is more suggestive of prostatitis or cystitis. That the appearance of the organism in the urine is often intermittent is due, in some cases, to a blocking of the ureter with débris. In children ureteric blockage causes high fever with rigors, and the most acute cases of pyelitis in infants sometimes yield negative findings until more than one examination has been made. The amount of associated pus is, to some extent, an index of the severity of the infection, and a regular quantitative estimation will show a diminution when the condition is improving. Bacilluria without cellular reaction is not uncommon; it is an extremely chronic condition and is resistant to treatment. In pyelitis the clinical condition usually shows marked improvement long before the urine ceases to contain organisms, and it may be urged that the only criterion of cure is a series of negative cultures over a long period. Even after a long period of freedom relapses or reinfections are liable to occur. The most hopeful cases for permanent cure are acute conditions in which the urine rapidly becomes sterile. Acute pyelitis is on rare occasions accompanied by profuse hæmaturia. Casts should suggest the possibility of pyonephrosis secondary to pyelitis. *B. coli* cystitis is usually secondary to pyelitis or to prostatitis. When the urine is offensive and, in addition to pus, contains a considerable amount of bladder epithelium as well as a fair quantity of mucus, cystitis should be suspected. The infection is frequently complicated by additional organisms such as streptococci and staphylococci.

Other Coliform Organisms.

Coliform organisms which for clinical purposes may all be classified as "atypical *B. coli*," are found in the urine with considerable frequency. The commonest of them is *B. proteus vulgaris* which is associated with chronic infections of the prostate, bladder, and renal pelvis. The significance of atypical organisms is apparently no more than that of ordinary *B. coli*, and conditions due to them should be treated in the same way.

Typhoidal Organisms.

Urinary carriers of typhoid and paratyphoid bacilli are not uncommon and the finding of the organism in the urine implies a renal focus of infection. The excretion of the bacilli is intermittent and may not be found by a single examination. The routine employment of litmus-lactose-agar medium sometimes identifies an unsuspected typhoid carrier. During active typhoid fever the bacilli are most commonly present in the urine from the third week onwards. It is a sound policy to insist upon three consecutive negative cultural examinations of the urine before discharging a typhoid patient as cured.

Staphylococci.

Staphylococci can always be cultivated from the urethral meatus and the first few centimetres of the urethra. Consequently staphylococci are frequent contaminants of non-catheter specimens of urine and a few may even be collected on a catheter during passage. The appearance of a few colonies of *Staphylococcus albus* on a culture medium can usually be disregarded.

Heavy staphylococcal infections are common as a sequel to the passage of an unclean catheter, as a secondary infection in genito-urinary tuberculosis, and as a superposed infection in renal or vesical calculus. Simple staphylococcal cystitis should never be regarded as a satisfactory diagnosis but should be looked upon as a direct hint to search carefully for a tuberculous lesion, for a calculus, or for a prostatic focus of infection. Staphylococcal cystitis, associated with stagnation of urine due to prostatic enlargement, results in ammoniacal decomposition of the urine. Staphylococci associated with hæmaturia and casts suggest infarction of the kidney with an infected embolus, particularly if the organism is of the aureus variety.

---

* Part I., Preliminary Tests for Infection, appeared last week.

Diphtheroid Bacilli.

These are meatal and urethral organisms and are not regarded in themselves as capable of producing a primary urinary infection. They are frequently found associated with a causal organism in cases of prostatitis and cystitis.

Streptococci.

The significance to be attached to the presence of streptococci depends greatly on the type of streptococcus found as well as on the clinical condition of the patient. Renal infarction in infective endocarditis results in the appearance of casts, red cells, and streptococci in the urine; it is relatively uncommon for the red cell content to be sufficient to be detected by the guaiacum test.

Apart from acute streptococcal septicæmia there is no doubt that small numbers of streptococci find their way into the blood stream in such conditions as acute tonsillitis, acute or generalised rheumatism, the early phases of broncho-pneumonia, or in heavy dental infections. The circulating organisms probably lodge as minute embolic foci in the kidney and they may be detected in cultures of the urine. The number present in the urine is usually small and there may be no other evidence of renal infection except an occasional red corpuscle. An elongated diplococcus, generally regarded as a variety of streptococcus, may be found at the urethral meatus, and is commonly present in the prostate, secondary to gonorrhœa. Cystitis may be caused by the same organism, usually in association with *B. coli*.

Gonococci.

Gonococcal cystitis is comparatively rare, particularly in males, and the presence of pus and gonococci in a non-catheter male specimen suggests urethritis or a ruptured prostatic abscess, unless the clinical symptoms point to an obvious cystitis.

Tubercle Bacilli.

Tubercle bacilli in the urine imply a tuberculous lesion of the genito-urinary tract requiring a thorough clinical examination in order to locate the exact site and extent of the disease. The question of confusion of *B. tuberculosis* with the acid-fast *B. smegmæ* is negligible and need not be considered if a catheter specimen is examined or if an acid-alcohol decolorising technique is used. The influence of early diagnosis on prognosis renders important a clear understanding of the limitations of the present bacteriological methods for detecting genito-urinary tuberculosis.

As a general rule, the appearance of tubercle bacilli in sufficient numbers to be found in a stained smear indicates an advanced lesion. It is therefore desirable to use every means for making a diagnosis before the condition has reached this stage. Earlier diagnosis may be made by guinea-pig inoculation, but even this method is not absolute, for it is estimated that from 10 to 160 living bacilli, according to virulence and type, must be inoculated into the animal before tuberculosis can be produced. Animal inoculation is thus a useful test, but is not conclusive, and it has the disadvantage of necessitating a delay which may last from 6–8 weeks. Frequency, hæmaturia, or pyuria all merit full investigation for a tuberculous focus. The most valuable and significant laboratory finding in early cases of tuberculosis of the urinary tract is an acid urine containing a small quantity of pus, with perhaps a few red cells, but with no bacteria demonstrable in films or cultures. It is not generally recognised how frequently secondary infection occurs in renal or cystic tuberculosis, and that acceptance of *B. coli* or staphylococcus as the primary infecting agent may lead to the missing of a case of tuberculosis. Whenever renal tuberculosis is suspected, it is bad policy to await a result from a bladder specimen before investigating ureteric specimens.

Other Organisms.

Adhesions with communications between the bowel and the bladder may occur with carcinoma of the rectum, with diverticulitis and, with typhoidal, dysenteric, or other ulcerative conditions. In such cases the bladder becomes infected with the fæcal flora and the urine contains a large variety of bacteria, the most suggestive of which are the obvious intestinal anaerobes. *B. pyocyaneus* occurs in chronic cases of cystitis or pyelitis, but is usually secondary to some more virulent primary organism.

The urine may contain *Brucella melitensis*, *Leptospira icterohæmorrrhagiæ*, and the ova of *Bilharzia hæmatobium*, in which case the diagnosis is obvious.

THE EVOLUTION OF HOSPITAL SCHOOLS:

COMBINED TREATMENT AND EDUCATION FOR CHILDREN SUFFERING FROM PHYSICAL DEFECTS.*

BY SIR HENRY GAUVAIN, M.D., M.CHIR. CAMB.,
F.R.C.S. ENG.,
MEDICAL SUPERINTENDENT OF THE LORD MAYOR TRELOAR CRIPPLES' HOSPITALS AND OF THE MORLAND CLINICS, ALTON;
AND
EVELYN M. HOLMES, M.B. MANCH.,
RESIDENT MEDICAL OFFICER, MORLAND CLINICS, ALTON.

(*Concluded from p. 792.*)

THE aim of education is to give to the crippled child as many of the amenities and advantages of ordinary school life as is possible, to encourage corporate life and the happy school atmosphere, whilst by specially selected methods endeavouring to "catch up" along the lines of education in normal elementary schools.

To the normal child education is its chief asset; how much more it meant to the cripple was not realised until it was tried. In hospital schools, too, it has been found to have a definite medical value. It makes periods of rest and exercise easy to regulate and keeps the child busy, interested, and happy. If by means of these educational facilities the cripple only gains and retains confidence in his relationship with the ordinary world the effort would be worth while, for it was the feeling of his inferiority, his inability to make a success of life, as much as his sensitiveness to an unsightly complaint that so overwhelmed and distressed him. But it does more than that. It enables him to enter into and profit by training in industrial occupations and take his stand both in the social and the industrial life of the nation when the time comes. It has been estimated that even with present facilities 80–90 per cent. of crippled children passing through special schools and training institutions are found able to compete for work in the open market. From being a menace to society the cripple had become an object of charity, but now the attitude has changed again and the cripple is being accepted as an instance of civic responsibility.

The Task Before Us.

Recent figures issued by the Board of Education with regard to physically defective children are of interest in showing how great the problem is. It is estimated that there are amongst elementary schools in England and Wales some 83,000 children for whom special provision should be made. Of these, according to the latest figures,[18] 65,230 are suffering from malnutrition, deformity, tuberculosis, or cardiac crippling, and the present accommodation, according to the same report, is: in open-air schools, 2078; *in cripple schools, 980; and in hospital schools, 3372;* leaving a residue of 58,810 of these cases still unprovided for.[19]

---

* A paper read before the Medical Officers of Schools Association on March 15th.

Special schools are now admitting, as well as a certain number of serious heart cases, a small proportion of debilitated children.

London has no residential school within its boundary; it utilises schools established by other local authorities and by philanthropic societies. Some conception of the extent of the work undertaken may be visualised when it is realised that the ambulance system for the day schools of the physically defective in London alone costs £35,000 per annum.[20]

Schooling and Treatment.

A number of residential schools for such children are now in existence, but these are not hospitals in in any sense of the word. The children are admitted to be housed and educated, not for treatment. Should any treatment of children in special schools be thought necessary, it is customary to send them into general hospitals. The orthopædic hospitals such as Heatherwood at Ascot, Mansfield at Northampton, Royal National at Portland-street and Stanmore, Treloar's at Alton, St. Nicholas at Pyrford, Shropshire at Oswestry, Wingfield at Oxford, and others provide schools with qualified teachers, and in some the organisation reaches a high point. But it is not essential that education be given in these hospitals. If the hospitals care to make suitable provision for the education of their children they may apply for certification as "special schools," under the Board of Education, and if sanctioned may also receive grants both[21] in aid of treatment and of education. Although seven new hospital schools have opened since April, 1927, the number of hospitals which receive orthopædic cases under local education authority provisions, and which do not offer educational facilities to the children, is as great as 44.[22 23] The inevitable result is that where education has not been provided this has to be "made up" to the child on discharge at much greater expense to the State.

It is now considered that not only are the great bulk of crippling defects preventable, but curable, and should the incidence of disease continue to diminish as it is doing at present, and for those children requiring treatment and capable of education the hospital school scheme be still further developed, the need for special schools as such would diminish.

Throughout the country, schemes for the detection, treatment, education, and after-care of the physically defective are ever extending. New schemes were approved by the Board of Education in 28 areas in 1927 making a total of 160,[24] but there are still 157 areas where no authoritative provision whatever has been made.[25] In practically every case the first move has been made by private individuals or voluntary associations, the local education authority stepping in afterwards and the two continuing to work in conjunction. The correlation of schemes involving various educational and health authorities, as well as voluntary associations for cripple children in the different areas and of different age-groups from infancy until the completion of their treatment and education, has been a matter of great difficulty. Much has depended on the voluntary workers. Indeed, it is the voluntary worker who has originated every advance that has taken place, for no Board of Education, or even Ministry of Health, dare take over such responsibility until its beneficial results are already a proved and certain fact. Surely this is a sound argument for the retention of our voluntary hospital system and the blending with it of State service.

In after-care work the voluntary associations are still almost wholly responsible in the matter of organisation and in finance, except for a substantial grant received by the after-care committees in the London area from the Ministry of Labour.[26]

Such work is of the greatest value. It is now for medical science to show how by taking every measure to prevent the onset of deformity, by sparing no pains to treat efficiently the crippling defects of childhood and by giving every possible educational facility to the child under treatment, the nation would be repaid for the expenditure incurred by the conversion of the cripple into a healthy, happy, and useful citizen. A national movement to complete the schemes for the physically defective throughout the country would never be regretted.

Open-air Schools.

An important movement in the interests of defective children has been the recognition of the value of open-air schools. The first of these was opened at Plumstead in 1907, others followed, and their results have been so excellent that the scheme is ever-widening and even being extended for the normal child by the provision of open-air play and classrooms. In the last report available it is stated that there is now accommodation for 6001 pupils in day schools and 2078 in open-air schools.[27] Some of these schools have advanced to the stage of being schools where sun-treatment is combined with open-air and education. The first open-air school in London to adopt sun treatment was Stowey House, Clapham Common, and the headmaster, Mr. Green, and his assistants, are enthusiastic and convinced of its value.

The *Times* of March 13th, 1929, abstracts the 1927 report of Mr. Gater, the Education Officer of the London County Council, which commends open-air schools, and referring to one in East London states: "The garden (*a former refuse dump*) is surrounded by docks, factories, a railway terminus, and old houses. The garden is now maturing and provides a pleasant background, making outdoor life for the subnormal child seem really worth while. Twenty-eight boys attended an open-air class, camping out in blankets during the winter with definite physical benefit. The boys showed no wish to return to the class-rooms."

The Latest Advances.

The latest advance in schemes for the physically defective child has been the widening of the scope of hospital schools to include other forms of physical defect beyond crippling as ordinarily understood. As examples may be cited the lupus wards at the Treloar Cripple Hospital, and hospital school accommodation for cardiac cripples and other debilitated children. There is unlimited scope for further extension in this direction, and fortified by the experience of the past there is no doubt that the next few years will see great developments. The need for a comprehensive register to include all defects amongst school-children requiring skilled treatment combined with education is now called for. In addition to the various crippling conditions records are needed of all cardiac and rheumatic cases, debility, malnutrition, intractable anæmias, bronchiectasis, asthma, diabetes, and other affections. Valuable preventive work would be done by open-air hospitals for the temporary accommodation, treatment, and education of children convalescing from debilitating diseases. Already it has been demonstrated that since prolonged in-patient treatment for cardiac cases has been in vogue, wonderful results have been obtained. Dr. A. P. Thomson, medical officer to Birmingham special schools, states: "Many cardiac lesions recover to a remarkable extent and many hearts that seem damaged for life recover in time and become normal, even in older children."[28]

The importance of this subject must be our apology for the length of this paper. We would like to have described in detail the hospital schools, the treatment adopted, and the type of education offered, differing according to the social needs of the patient as well as by reason of their disabilities. One point, however, must be emphasised. The hospital school, for whatever class of children it caters, must be in the country or at the seaside and not in a town. It must be conducted as an open-air institution to raise the metabolism and increase the vigour and physical fitness of the pupil. Intermittent sun treatment should be employed for both its effect on the mind and the body. We regard its value in evoking mental activity as at least as great as its influence on bodily defects.[29] [30] Further details of treatment or education we may not pause to discuss.

For a child to derive full benefits from education, he or she should, if showing a pathological divergence from the normal, be restored as speedily and as fully to the normal as is possible, and during this process, if that is necessarily lengthy, education modified to, and planned for, his particular needs should be available. But the doctor must lead the way. The responsibility is primarily his and he will find the intelligent teacher eager and willing to coöperate if taught how. The hospital school for all classes of the community is the most urgent need of every physically defective child and is of equal or greater importance to such a child or adolescent as is the ordinary school or university to its normal pupil. During the past 20 years over 5000 physically defective children have been under the care of one of us (H. J. G.) for combined treatment and education or training. Brief notes on a few such illustrative cases will afford tangible evidence of the value of such care.

Cases from the Treloar Hospital (Elementary School Type).

A. B., a cachectic girl, admitted May, 1918, with tuberculous disease of the hip with abscess formation. Discharged September, 1920, with disease arrested, no deformity, hip fixed by fibrous ankylosis. This child was exceptionally intelligent, as is shown by the following extracts from a letter from her:—

"I think you will be interested to hear something of the career of an old patient of yours at Alton, if only because it forms a not uninteresting example of the difference which Alton may make to any individual. . . . I left in September, 1920, when almost 14 years old. When I had been at home a few months I was sent to school and placed in a form of girls of my own age, although, of course, I was far behind them. In 1925 I obtained from Southampton Girls' Grammar School the Rooper scholarship tenable at University College, Southampton. . . . In June of this year I sat for the B.Sc. (Econ.) examination of London University and obtained the only first-class honours degree given on the external examination, and was awarded the Gladstone Memorial prize. During this autumn I was given the Metcalf studentship by London University to enable me to undertake research at the London School of Economics. . . . While I am conscious that this catalogue of my achievements sounds very like self-advertisement, I am far more conscious of its being an advertisement for the good done me at Alton, and for which I shall always be grateful."

C. D., a cachectic freckled boy, aged 11. Admitted April, 1919, with cervico-dorsal caries and paraplegia. Discharged February, 1921, with the disease arrested, no deformity. The boy subsequently emigrated to New Zealand, and in a recent letter writes as follows:—

"I can now do as good a day's work as anyone, harvesting or anything at all. . . . I've got a ripping horse of my own, a six-year-old bay filly, so I'm always out after deer and fish. I can ride in great style now, although my horse runs away with me now and again—she's a bit flighty."

We could give hundreds of examples of a successful and happy career following treatment. One girl sent by the late Dr. F. E. Batten with spinal caries and psoas abscess is now one of the leading lady lawn-tennis champions. Here is a case illustrating treat-
quantity of education in the hospital and training in
with no bacteria
It is not generally recog cripple, admitted to hospital with

primary infecting agent may lead t: First started work
case of tuberculosis. Whenever re en commenced busi-
is suspected, it is bad policy to await ut now good, and was employing a
bladder specimen before investigat whom had been

The training given to the lads in the College brings out most remarkably their self-reliance and resourcefulness. Though handicapped by their physical disabilities not only do they become good citizens, but extract from life pleasures from which it might be supposed they would be debarred. As an example, *Cycling* for January, 1928, reports a cyclist (an old trainee at the College) who had cycled 8308 miles in the year with only one leg, his longest day's run being 123 miles. This boy is now a successful journeyman tailor.

Cases from the Morland Clinics (Secondary and Public School Type).

H. I., a girl of 14, admitted with tuberculous disease of the dorsal spine and complete paraplegia. Treatment combined with education occupied two years. Recovery without deformity. Became head girl of her school and captain of the tennis and hockey teams. Was last seen six years after leaving school. She had that day played two rounds (18 holes each) of golf. Remains perfectly well.

J. K., spinal caries with deformity and psoas sinus. Had been recumbent for ten years. Very cachectic on admission. Sinus healed in six months. Deformity reduced and imperceptible. Treatment 15 months. Was coached for "little-go" while being treated, and entered Cambridge University. At Cambridge distinguished himself as a daring *motor-cyclist racer. Graduated. Now in partnership* of an important firm and displaying great business ability.

L. M., spinal caries with extreme deformity. Paraplegia and incontinence for seven years previous to admission. Cord completely destroyed as shown by laminectomy. Later excelled at archery, passed high in his tripos at Cambridge. Entering on a specialised legal career, which should be highly useful and remunerative because of his special gifts, though he necessarily remains paraplegic. Drives his own car by hand control.

In less severe cases equally valuable results may be achieved in much less time, e.g.:—

A boy, otherwise healthy, with lupus vulgaris on the forehead which had resisted all treatment. Of a naval family it was desired that he, too, should enter the Navy. Treated by Finsen light while preparing for examination. Lesion healed with satisfactory cosmetic results, was passed by doctor, and became a naval cadet. The time factor for treatment was here of special urgency.

A public school boy developed severe cervical adenitis. Admitted for treatment which occupied six months and returned to his school cured and without scarring. Meanwhile, he had been specially coached in weak subjects.

Numerous cases of girls with acquired scoliosis have been treated and meanwhile educated and enabled to return to their ordinary school.

Further examples of such cases might be multiplied almost indefinitely, but the foregoing are sufficient to demonstrate the value of combined specialised treatment and education. Numbers of physically defective boys and girls have had combined treatment and instruction enabling them to proceed to ordinary schools or universities, or, when disability has occurred during their school career, have been able, after treatment combined with education, to complete their education at their original schools or go direct to the university with their disabilities rectified and with the minimum disturbance of their education. The importance to these children of education during treatment will be readily appreciated.

LOCAL GOVERNMENT ACT, 1929.

THE FIRST CIRCULAR TO LOCAL AUTHORITIES.

IN addressing to local authorities the first circular[1] on the subject of the Local Government Act, 1929, which became law on March 27th, the Minister of Health makes some general observations on the content and significance of the Act as a whole.

The Transfer of Poor-law Work to Local Authorities.

The most far-reaching change is the transfer to the responsible local authorities of the work which for nearly a century has been organised under a distinctive name and under separate legislation by the poor-law authorities. The transfer will have its most significant effect in bringing about a new situation under which the local authorities—

1. Are made responsible for vaccination;
2. Are made responsible for infant life protection;
3. Are made responsible for the collection of the fundamental vital statistics; and
4. Are made responsible, severally or jointly, for the provision, maintenance, and management of all public institutions for the cure or mitigation of physical or mental disease.

Under the last head there pass to county borough councils and (subject to local arrangements as to management) to county councils, many thousands of beds for sick and mentally infirm patients in separate infirmaries and other institutions; and it must be remembered, in conjunction with this transfer, that security is taken for the proper provision in future of beds for infectious diseases for the inhabitants of every county area either by one of the authorities (the county or district council) for the area, or by some other authority who have beds to let on agreed terms.

At the same time the vital importance of retaining the personal touch in the administration of poor relief finds recognition by the provision made in the Act for guardians committees in county areas, doing the actual work of relief locally in close contact with the recipients of relief, and being constituted to a defined extent of members of the county district councils.

The New Organisation of Poor-law and Public Health Work.

By the transfer to them of the responsibility of poor-law authorities for the treatment of the sick poor in institutions, in conjunction with the enlarged powers now conferred upon them to provide hospital accommodation for all types of cases, and to organise properly the provision and use of infectious diseases hospitals, local authorities are placed for the first time in a position to survey the whole of the public hospitals in their areas, and to use them to the best advantage in the light of the principles which Mr. Chamberlain summarised as follows in moving the second reading of the Bill:—

> "The whole trend of practice in modern medicine and surgery is towards the treatment of many cases in institutions, where there can be accumulated the specialised equipment and specialised skill which are not always available in private homes. When this Bill becomes law we shall have a position in which there will be one single health authority in each area whose duty and function it will be to survey the whole institutional needs of that area. They will have at their disposal all the institutions which are now in the hands of the guardians, in many of which the accommodation is not fully occupied. They will have an opportunity of reclassifying their institutions, of closing such as are no longer suitable for modern requirements at all, of altering and adapting others and using one for one purpose and another for another purpose. Even to-day there is a certain amount of classification attempted in many of the institutions of the guardians, particularly in the large areas, but I think it must be clear to everybody that, with the small numbers that are to be found of each particular kind of case in any particular institution, it is quite impossible either to get the sort of classification that you want, or to bring to it that equipment and that specially skilled staff and nursing which is essential if you are to get the best results."

Local authorities are required by the Act, in preparing administrative schemes for carrying out the work in relation to the provision and use of public hospitals, and the other work, transferred to them from poor-law authorities, to have regard to the desirability of securing that, as soon as circumstances permit, any assistance which can lawfully be provided otherwise than by way of poor-law relief shall be provided exclusively by virtue of the several Acts specified in Section 5. A clear direction is thereby given that the process known for the last 20 years as the break-up of the poor-law shall be put in hand in a practical manner and carried so far as the existing law and the prevailing circumstances allow.

Further amendments of the law directed to this end are not, of course, excluded or rendered more difficult by this provision, but certain criticisms were made in Parliament during discussion of the matter on the two points (1) why the law governing the relief of the poor (as distinct from the responsibility for administering that law) should not first be transformed before being transferred to new authorities to administer; and (2) why the process conveniently termed the break-up of the poor-law should not be made compulsory upon all the new authorities at once.

In reply to criticism on the first point Mr. Chamberlain has expressed the view that any question of the amendment of the law under which poor relief is provided can more profitably be discussed and determined after the new authorities have had a reasonable opportunity of familiarising themselves both with the statute law as it stands in the consolidating Poor Law Act of 1927, and with the subordinate legislation bearing on the transferred work, and of considering their powers and obligations in this new sphere in the light of their general experience of local administration.

In meeting criticism on the second point, Mr. Chamberlain has thought it reasonable to urge not only that a direction to local authorities to use their alternative powers of giving assistance always, and at once, in one manner only, would be out of harmony with the basic principle of the Act that the responsibility of authorities for the conduct of local affairs should be respected and enlarged; but also that such a direction, if given, must, in some areas at least, be disregarded, because the accommodation in institutions at the disposal of the authorities in the first instance, even after the transfer to them of poor-law work, will not suffice to enable them in every case to provide assistance which takes the form of institutional treatment except by way of poor relief.

The Future of Public Health Work in Counties.

After more than 50 years of discussion and unsatisfactory progress, definite provision is made to secure to every county district council at the earliest possible moment the services of a medical officer of health whose attention will be concentrated upon public duties. The inhabitants of the poorer parishes and districts are for the first time afforded the alternative possibilities either of securing the acceptance by others of a share of any undue burden which the cost of providing themselves with a water-supply or sewerage would impose; or even, in the last resort, of arranging that the management of services such as these shall be concentrated in the hands of county councils, if that course is found most advantageous in practice to health and well-being. Full facilities are afforded under the Act for preventing dispersal of money and effort intended for the welfare of mothers and children in the several parts of any county, by concentrating work directed to that end in the hands of those authorities who are in a position to undertake, if not the whole, at least some substantial portion, of the services which go together to form the basis for systematic arrangements of this nature (notification of births, provision for maternity and child welfare, school medical work, and supervision of midwives).

---

[1] General Circular on the Local Government Act, 1929. No. 1000. H.M. Stationery Office. 3d.

Consultation between Local Authorities and Local Bodies representing Voluntary Hospitals.

In many areas the guardians have, in the exercise of their duties under the poor-law, provided separate infirmaries which in some areas are already equipped up to the same level as the voluntary hospitals of the area, and in others are rapidly approaching that level. To an increasing extent admission to these infirmaries has been provided on repayment terms for members of the community who cannot be said to be destitute otherwise than to the extent that they have need of expert medical assistance, cannot afford to obtain it in a nursing home, and cannot obtain immediate or early admittance to a voluntary hospital. In any area in which a poor-law institution of this type is to be transferred to the local authority, whether the local authority do or do not make a declaration under Section 5 of the Act, the problem of finding means of coöperation with the voluntary hospitals in the area obviously arises, and it will also certainly arise in other areas where the provision of a self-contained public hospital by way of poor relief or otherwise, or the expansion of existing buildings on hospital lines, is a matter requiring consideration in the interest of the inhabitants.

The provisions of Section 13 of the Act secure that by consultation between the local authorities and local bodies representing voluntary hospitals the provision and use of hospital accommodation in every area is not achieved to the accompaniment of any unnecessary and wasteful competition between public and voluntary bodies. It will accordingly be incumbent upon the council of every county and county borough, when making provision for hospital accommodation in discharge of the functions transferred to them from poor-law authorities, to consult such committee or other body as they consider to represent both the governing bodies and the medical and surgical staffs of the voluntary hospitals providing services in, or for the benefit of, the county or county borough, as to the accommodation to be provided, and as to the purposes for which it is to be used.

Mr. Chamberlain, it is stated, attributes the greatest importance to the proper carrying out of this section. In making the necessary institutional provision for the health of the people, it is imperative that local authorities should establish the most cordial relations with, and should make the fullest use of the accumulated skill and experience of, the medical profession in regard to hospitals.

The last sentence of the circular reads: "It is the confident hope and expectation of the Minister that as procedure under Section 13 becomes established and regular, it may lead to wider arrangements for the fullest consultation between the local authority and the medical profession, not merely in regard to institutional accommodation and its use, but also in regard to those numerous developments in the health provision of the people which are implicit in the new organisation laid down by the Act."

MEDICINE AND THE LAW.

Liability for Notification of Birth.

A PARENT was fined at Mortlake police-court on April 10th for having failed to notify the birth of a child last December to the medical officer of health for Barnes. The liability arises under the Notification of Births Act, 1907, originally an adoptive statute, but made to apply generally throughout Great Britain in 1915. This Act is an addition to the other statutory requirements for birth registration. It makes it the duty of the father of a newly-born child, if he actually resides in the house where birth takes place at the time of its occurrence, to send written notification to the medical officer of health within 36 hours. The Act says that the local authority is to supply stamped addressed postcards free of charge to any medical practitioner or midwife practising in that area who applies for them. The wording of the statute is somewhat vague. After setting forth the duty of the father, the Act says the same duty is imposed on "any person in attendance upon the mother at the time of or within six hours after the birth." As is suggested in "The Conduct of Medical Practice," the intention must be to make the father primarily liable (provided he is actually living in the house when birth occurs), the medical practitioner being liable (qua person in attendance) if the father defaults. It is advisable for the doctor to bear in mind his responsibility to notify (*a*) if the father is absent from home, or (*b*) if the father has failed in his duty. It is a good defence under the statute if either father or doctor "satisfies the court that he has reasonable grounds to believe that notice has been duly given by some other person." That was the father's attempted defence at the recent proceedings at Mortlake; he said he thought the doctor had made the notification "as was generally the case"; he had himself been ill at the time owing to a motor accident; and the child had died shortly afterwards. The clerk to the Barnes District Council pressed for the maximum penalty of 20*s.*; he said that the father had been written to on the subject several times and that, as the council had had several similar cases recently, it was decided to prosecute in order to make an example of him. The bench imposed a fine of 5*s.* with 6*s.* costs, which seems to show that the magistrates did not take a very grave view of the offence.

Medical Inspectors in Divorce Cases.

In Stroud *v.* Stroud otherwise Grantham, recently reported in the *Solicitors' Journal*, a decision was given on the method of appointing medical practitioners to examine parties concerned in matrimonial causes at assizes. It may be remembered that in 1920 Parliament allowed divorce cases to be tried at assizes instead of in the divorce court in the London law courts. This has undoubtedly lightened the work of the court in London; it has also proved economical because the parties and witnesses can attend for trial nearer their own homes. Under the Poor Persons Rules (Order XXXVA of the Rules of the Supreme Court) a "poor person" can begin his action under the Matrimonial Causes Acts in a district registry instead of in London. One such case, in which there was an undefended petition for nullity of marriage on the ground of the wife's impotence, was tried at Lewes Assizes last December. The District Registrar appointed two local doctors practising at Eastbourne to examine the parties and report to the court. These two practitioners were not on the official rota of medical inspectors for the Divorce Division and, although the case was in other respects free from difficulty, Mr. Justice Rowlatt postponed the drawing up of the decree nisi until after he had heard argument on the question of the District Registrar's authority to appoint practitioners outside the rota. In February the point was argued. The petitioner had to support the action of the district registrar on which the evidence for the decree had been based. It was argued on his behalf that the court's matrimonial jurisdiction was historically ecclesiastical in origin; the appointment of medical inspectors, according to the former ecclesiastical practice, would be a matter for the registrar; under the Poor Persons Rules, where a matrimonial cause is begun in a district registry, the district registrar is deemed to have the powers of a registrar in the Divorce Registry in London. The Judicature Acts have of course modernised the legal system considerably; but both Section 23 of the 1873 Act and Section 32 of the 1925 Act (which consolidated the previous enactments) declare that, when no special provision to the contrary is to be found in the statute or in rules of court, any jurisdiction is to be exercised as nearly as possible in the same manner as by the court to which it formerly appertained. Mr. Justice Rowlatt accepted the argument and held that the district registrar had had full power to appoint the practitioners who acted as medical inspectors.

Swab Left in Patient's Body.

At a recent inquest at Llanidloes it appeared that the deceased had undergone an operation at Ebbw Vale Hospital last December, and, having gone to Llanidloes for convalescence and still feeling ill, had been operated upon again at Llanidloes Hospital. Dr. Milwyn Burrell, who performed the second operation on March 21st, before the patient's death, described the finding of a large pack or swab in the abdomen. He considered death was due to ulceration of the intestines from irritation caused by the swab. Asked if he regarded himself as responsible for counting all instruments and swabs at an operation, Dr. Burrell replied that the surgeon could not do this; he must leave it to someone else; the common practice was to leave it to the theatre sister. It was, he said, the surgeon's duty before closing the wound to inquire if all instruments and swabs are accounted for. Dr. John Dunlop, of Abercarn, who performed the operation in December, described the operation and said he removed all the swabs he could see. Dr. James Sullivan, who was assisting, asked: "Are all the swabs out?" and the answer "yes" was given; he did not know by whom. Dr. Dunlop said he then closed the wound; he thought the patient's heavy breathing might have sucked in the swab and in the necessary hurry this one had been overlooked. The matron of the Ebbw Vale Hospital described what was done at the first operation. The jury found that death was due to a swab being negligently left in the patient's abdomen at the operation in December, but they added their opinion that the negligence was not of a criminal nature.

IRELAND.

(FROM OUR OWN CORRESPONDENT.)

Public Health in the Free State.

THE vote for the Department of Local Government and Public Health, which was taken in the Dail last week, gave deputies an opportunity to criticise the work of the department. In proposing the vote of £302,556, the Minister said that there was an increase of £59,915 for housing. There was a slight decrease for other services. The contribution for social services amounted to £106,396, including maternity and child welfare work, medical treatment, meals for school-children, and treatment of tuberculosis. The department had no reason to be dissatisfied with the appointment of medical officers of health, who were now being appointed in many counties. He had before him a draft Bill dealing with the reports of the Poor-law Commission and the National Health Insurance Committees, but he was not in a position to say when these Bills would be presented to the House.

Mr. S. O'Kelly, in moving that the estimates be referred back, said that there was not enough money available for the requisite social services. The infant mortality in Dublin was 118 per 1000, and something should be done to remedy that. Dr. O'Dowd drew attention to a grave outbreak of enteric at Carrick-on-Shannon, due, he suggested, to contaminated water-supply. Sir James Craig urged that there should be a Minister, or at least a Parliamentary Secretary, for public health, who had had a medical training. He said that the sanitary condition of some of the small towns and villages was deplorable. He asked what progress had been made in the medical inspection and treatment of school-children. Mr. O'Reilly called attention to the malnutrition exhibited by many school-children, and to the lack of sanitation and water-supply in towns and villages where fairs were held. Dr. Tubridy spoke of the need for improved housing in rural as well as urban areas, and complained of the unsuitability and lack of equipment of rural dispensary premises. Dr. Hennessy suggested that the importance given to a knowledge of the Irish language led to the appointment of relatively inferior medical officers. They should see that the best doctor was appointed, irrespective of any language. He agreed that in an Irish-speaking district a doctor should know Irish to discharge his duties efficiently. Nevertheless, too much attention should not be paid to language. "Veterinary surgeons were notorious for making accurate diagnoses of their cases, and they did so without conversation with their patients."

The Minister, Mr. R. Mulcahy, in reply, deplored the lack of public education in the country in regard to sanitary matters. He expressed some doubt as to whether the grants given to mental hospitals might not be more usefully employed in some other service which got more closely to the root of the prevention of disease. The vote was carried.

BERLIN.

(FROM OUR OWN CORRESPONDENT.)

Syphilitic Infection of a Pathologist.

AN assistant pathologist at a municipal hospital contracted syphilis as a result of making a post-mortem examination of a child who had died from the disease. He therefore brought an action for damages against the city and the chief pathologist. In support of his plea that there is danger of syphilitic infection at autopsies he quoted cases from the literature, and he claimed that the city was under an obligation to protect the dissecting staff against infection. It was the rule in other pathological institutes, he said, to wear rubber gloves and he had repeatedly asked the chief pathologist for permission to do so. The chief pathologist, however, had always denied that syphilis could be transmitted by dissection and had mocked at the idea of prosectors using gloves. Although he had not actually prohibited the wearing of gloves he had by his conduct made it almost impossible for his inferior to use them. By saying, moreover, that cases of syphilitic infection at post-mortem examination had hitherto neither occurred nor been reported, and by diagnosing the plaintiff's chancre as an ordinary post-mortem tubercle, thus causing a delay in the use of antisyphilitic treatment, the chief pathologist had impaired his assistant's health and had acted negligently. The city authorities had been guilty of great negligence, too, in not providing satisfactory gloves. Only after the accident had new gloves been furnished.

The defendant said that he had not at all prohibited the use of rubber gloves which had always been at the disposal of his assistant. According to many pathologists dissecting with gloves was sometimes more dangerous than without. The plaintiff had shown his injury to him only a month after the dissection, and being a medical man he ought to have ascertained the nature of the disease himself.

By an injunction the defendants were ordered to pay the plaintiff 600 M. (£30) a month, but on appeal this decision was quashed. In judgment it was stated that in the expert opinion of several pathologists syphilitic infection from this cause was extremely rare and wearing of gloves did not give absolute protection. The chief pathologist had made no order prohibiting the wearing of gloves, and the plaintiff had been very careless in not consulting a medical man from the beginning, relying instead on the opinion of his chief, whom he knew not to be a practitioner. The chief pathologist and the city were thus held not responsible for the accident and its sequels.

The Use of the Soya Bean.

Germany has to pay an enormous sum of money every year for the importation of products destined directly or indirectly for food, and especially for proteins and fat. Dr. Oppenheimer therefore urges the advantages of the soya bean, which is cultivated, especially in Manchuria, as a source of food. A meal prepared from the bean contains 45 per cent. of protein and 22·4 per cent. of fat, and thus has four times more protein than wheat flour and 20 per cent. more calories. It is the cheapest available form of food. Instead of importing meat, eggs, milk, and cheese at a cost of 700 million marks Germany could get the same amount of protein and fat by importing 400,000 tons of soya bean at one-seventh of the cost. Soya meal may be used for making puddings, bread, and cheese, and also may be added to the ordinary rye bread to make it richer in protein. The difficulty would be that the workman not only wants to eat, but also to see, smell, and taste his food, and therefore it is highly probable that he would eat soya bread sandwiches with fat from America and sausage made from pigs fed with corn from the Argentine, thus making useless the importation of soya as a substitute for these products. Soya bean might, however, be of great value in cases of urgency where a population has to be saved from starvation, and for poor people's kitchens and the like.

Hypervitaminosis.

Prof. R. Fischl and Dr. B. Epstein [1] report experiments on the effect of a preparation of irradiated ergosterol (vigantol) on rabbits. They point out that hypervitaminosis has been observed after the indiscriminate use of this substance, manifesting itself by disorders of the myocardium, kidneys, and other organs. To ascertain the effect of irradiated ergosterol on healthy rabbits they administered five drops of vigantol oil twice daily to three rabbits 3 months old. One of the rabbits died after five days, showing on dissection a calcification of the vessels and of other organs. The second rabbit died after 15 days, with severe emaciation and an intensive sclerosis of the ascending aorta and the vena cava. The third rabbit died after a month and had an enormous swelling of the liver with disseminated foci of cartilaginous consistence. Microscopical investigation proved that there was necrosis and calcification of the parenchyma without parasitic invasion. While rabbits are very sensitive to vigantol guinea-pigs have a relatively high tolerance. It follows from these experiments, however, that vigantol is not an innocuous remedy in large doses, but has a powerful action in mobilising calcareous substances in various organs. It may lead to severe morbid conditions endangering life. Rabbits with rickets do not stand administration of the preparation better than healthy animals. Although the results of the experiments cannot be applied without reserve to the human species they must lead to a cautious administration of irradiated ergosterol. Fischl and Epstein declare that from their experience in the Pædiatric Clinic of Prague University they have not formed so high an opinion of the prophylactic and therapeutic value of vigantol as have other authors. They think that the time has not yet come for allowing its general use.

How to Keep Young.

Prof. Fürbringer, former chief physician to the Friedrichshain Municipal Hospital at Berlin, gives rules for prolonging life based on his own experience. Physical exercise he regards as very healthy; at the age of 80 he continues to indulge in a walk of 10–20 kilometres twice a week, and still climbs in the Alps, swims in summer, and skates in winter. He has reluctantly given up cycling on account of the street traffic in Berlin. Muscular over-exertion, however, must be avoided; whilst food should be poor in fat and salt, and he disapproves of the consumption of much milk. Abstinence from spirits and tobacco is, he thinks, unnecessary, and he prefers temperance. To the soundness of his advice Dr. Fürbringer is himself a testimony, for he is still in practice and regularly attends the meetings of the medical and other societies where he often takes part in the discussions.

Prophylaxis of Whooping-cough.

Dr. Bernuth, of the Pædiatric Clinic of the University of Jena, has experimented on the prevention of whooping-cough by means of a vaccine made from the Bordet-Gengou bacillus. The preparation is sold under the name of tuscosan in ampullæ of 1·0 c.cm., containing doses of 25 to 350 million organisms. The injections are made at intervals of three to four days, and Bernuth says that local rashes are rarely observed and usually disappear within a short time. In five of seven cases in which whooping-cough was imported into the clinic a spread of the disease among other children was avoided. Of 70 inoculated children who came in contact with the patients suffering from whooping-cough only four infants of a few months' old caught the disease. The vaccination is effective for a short time only, infection being possible again some months afterwards. It is desirable to vaccinate as early as possible, but if inoculation fails to prevent the disease it is said to modify the severity of the symptoms.

The Liberal Professions and Unemployment Insurance.

As a result of a resolution adopted in Parliament the Minister of Labour has made inquiries whether it is necessary to include the liberal professions under the insurance against unemployment. Among other bodies he has approached the Hartmann-Bund to ascertain their opinion, and they have answered that there is no need for the medical profession to be included in the unemployment insurance. The profession, they point out, is not a trade-union, but a free profession which has organised, and will continue to organise, the support of its members in cases of necessity without official interference.

The Services.

ROYAL NAVAL MEDICAL SERVICE.

Surg.-Comdr. T. W. Jeffery is placed on the retd. list with the rank of Surg. Capt.

ROYAL ARMY MEDICAL CORPS.

Maj. J. R. Yourell retires on retd. pay.
Lt. on prob. D. C. MacE. Macpherson resigns his commn.
S. W. Gabbe to be Temp. Lt.

ARMY DENTAL CORPS.

Capt. A. T. Madin to be Maj.

ARMY RESERVE OF OFFICERS.

Lt.-Col. W. C. Croly, having attained the age limit of liability to recall, ceases to belong to the Res. of Off.

SUPPLEMENTARY RESERVE OF OFFICERS.

Lt. J. V. Dockray to be Capt.

TERRITORIAL ARMY.

Capts. H. V. Walsh and K. Pretty to be Majs.; M. De Lacey to be Lt.

Supernumerary for Service with O.T.C.: Capt. V. C. Pennell resigns his commn. and is regranted the rank of Capt.

ROYAL AIR FORCE.

A. P. Atkins (temp. Lt. General List, Army, Dental Surgeon) is granted a temp. commn. as a Flying Officer (Dental) on attachment to the R.A.F.

BRITISH MEDICAL ASSOCIATION: AN ART EXHIBITION.—By the kindness of the Salford Corporation it has been made possible to arrange for an art exhibition to be held at the Salford Art Gallery in Peel Park, during the Annual Meeting of the British Medical Association in Manchester. It is proposed that this exhibition should consist of works of art (painting, sculpture, china, and other results of artistic production), either belonging to or executed by members of the profession, or having a special medical interest or association. The Executive Committee will be glad to hear at an early date from any member willing to loan, or influence the loan of, any such work of art. The Salford Corporation have undertaken the insurance and transport free of cost to the lender, the only condition being that objects lent must be left on view for two months. All communications on this subject should be addressed to the chairman, Local Entertainments Committee, B.M.A. Annual Meeting, 33, Cross-street, Manchester.

Correspondence.

"Audi alteram partem."

THE "PHYSIOTHERAPY CLINIC" AND THE PRACTITIONER.

To the Editor of THE LANCET.

SIR,—The relationship between the practitioner on the one hand, and the establishment which provides physiotherapy or the medical man who specialises in this branch of treatment on the other, would appear to be somewhat ambiguous. With the expected increase in the number of such institutions as well as of medical men who devote their attention to this work, the position may well become a little strained. If the difficulties that have arisen, and may still arise, could be ventilated, a useful purpose might be served and the ethical situation become more clearly defined.

The position, as I see it, is much as follows: A practitioner sees a patient and decides that some form of physical treatment is necessary. Having none of the necessary apparatus at his disposal, he has either to send his patient to some institution which provides the requisite treatment or to a colleague who practises in one or other of these branches. In the first case the establishment selected may be run by some unqualified person who may or may not profess to confine his or her activities solely to patients recommended by a medical practitioner. In such an institution there may be no medical supervision of any sort and the patient is left entirely to the tender mercies of a half-trained or ignorant attendant. On the other hand, from the practitioner's point of view, there are advantages, in that he is not likely to lose his patient because he naturally exercises a certain amount of supervision during the course of the treatment. In such an institution the fees are apt to be lower because the services of a qualified man have not to be allowed for in fixing the amount of remuneration demanded by the proprietor of the establishment. If an institution, under medical supervision is selected, the fees are naturally higher and patients of limited means are liable to feel that there is no necessity to pay two doctors where one would do. The consequence is, that the practitioner who sends the patient sees very little more of him.

Then, again, there is a very decided prejudice on the part of many practitioners against having their prescriptions for physical treatment criticised by another doctor who by a look or a word may convey to the patient the impression that their particular doctor knows very little about the subject. Of course, it will be at once urged that such a thing cannot happen between professional colleagues. It does, however, and I venture to suggest that such a possibility is largely responsible for the success of many institutions that have no medical supervision. Of course, there are certain procedures that can only be satisfactorily carried out by a qualified medical practitioner who possesses special knowledge—e.g., X ray work and the applications of radium. Such work should never be left to unqualified persons, and for the practitioner who sends the patient to give instructions as to dosage would be entirely superfluous if not presumptuous. If I write a prescription for a bottle of medicine, I should consider it an intolerable proceeding if the pharmacist who dispenses it showed it to another medical man, and asked his opinion as to its suitability. Surely it should be possible to so arrange matters that medical men may be enabled to send their patients for treatment to institutions where their instructions will be carried out exactly as they are intended, without comment.

Take, for instance, the spas of this country. I know of no case where there is any medical supervision of a bathing establishment. The local practitioners send their patients to the baths for treatment and can rely on the written instructions being accurately carried out. The patient reports to his doctor at intervals during the course of treatment and the prescription is modified from time to time as occasion requires. I contend therefore very strongly that such provision for the supply of physical treatment should be made with regard to the large towns. Of course, I quite realise that in institutions where a definite claim is made for the treatment of certain diseases an adequate medical staff is absolutely essential. Patients are sent to such establishments for a definite purpose. They are sent by their doctors for the fullest investigation and treatment. The medical staff must of necessity have a free hand, and any outside interference would entirely defeat the objects of the institution.

Coming now to the question of the relationship between medical men who specialise in physiotherapy and their professional brethren, the position is difficult. The difficulty is mainly financial. Should the physiotherapist charge consultant's fees? If he does, someone is going to suffer besides the patient, and it is easy to guess who that someone is likely to be. At any rate, it will not be the specialist. The position teems with difficulties. If the patient is sent for an opinion as to the best form of treatment advisable, then the usual consultant's fees are obviously allowable. If a patient of limited means consults me and I consider that a course, say, of diathermy is indicated, I naturally hesitate before sending him or her to a professional colleague, who every time the treatment is given will demand much the same fee that I would for a consultation. I look around for some means of saving my patient's pocket, and if I send him to an unqualified person I expose myself at once to the charge of encouraging irregular practitioners.

Some solution should be found for what appears to me to be a difficult situation.

I am, Sir, yours faithfully,

MATTHEW B. RAY.

Bentinck-street, W., April 10th, 1929.

THE EMPLOYMENT OF BACTERIA IN MODERN WARFARE.

To the Editor of THE LANCET.

SIR,—I cannot help thinking that it would be more gracious if we were all to accept unreservedly the reassurance of our German colleagues in regard to the alleged employment by them of bacteria as a weapon on the Western Front. After all, an entry in an historical work is not really "evidence," and the best historians are fallible. To me it has always seemed impossible to believe that the German Staff, with their high scientific acumen, could have been so shortsighted as to employ a weapon as likely to be lethal to their own troops as to ours. The trench rats did not regard "no man's land" as a boundary. I would go further and suggest that the passage quoted by Lord Moynihan may itself have been inadvertently inexact. In 1917 the late Prof. Adrian Stokes (then in charge of a mobile laboratory) examined a dead rat with enlarged glands. He isolated a bacillus like that of plague. An expert was sent from Boulogne who said it was not in the least like plague, but next day returned and said he was uncertain. The specimens were sent to the Pasteur Institute, where they were reported as indistinguishable from plague. Can this incident have provided the basis for the story quoted? I was intimately associated with Adrian Stokes then and later, but I never heard it suggested that the rat in question was dropped from a balloon. Finally, no British army authority, bacteriological or administrative, has come forward to supply such details as might endow the passage quoted by Lord Moynihan with something approaching scientific accuracy. Without such details I, for one, could not associate myself with Lord Moynihan's unseasonable verdict.

I am, Sir, yours faithfully,
Wimpole-street, W., April 12th, 1929. J. A. RYLE.

To the Editor of THE LANCET.

SIR,—Lord Moynihan very rightly assumes that Prof. Pfeiffer and Prof. Prausnitz are competent "to listen dispassionately to evidence, to examine it critically and to give a true verdict." The evidence he asks them to consider is the isolation at a British field laboratory of *plague-like* bacilli from material dropped by a German balloon in January, 1918. One would have thought it unnecessary to point out to Lord Moynihan that no dispassionate bacteriologist would attach the slightest importance to this evidence without very material amplification. Has he further information regarding this plague-like bacillus, the circumstances of its isolation, and particularly of the material from which it came? Was it really *B. pestis*? The gulf between plague-like and plague bacilli may be a narrow one to Lord Moynihan. To the expert it is a gaping chasm.

I am, Sir, yours faithfully,
J. C. G. LEDINGHAM.
Lister Institute, London, S.W., April 13th, 1929.

To the Editor of THE LANCET.

SIR,—I have read with much regret Lord Moynihan's letter under the above title in your last issue. I am afraid it may mislead a section of the public into the belief that it has been proved that the Germans attempted to infect the allied armies with cultures of virulent bacteria during the recent war. The reiteration of this charge clearly suggests that the probable alternatives are either that the Germans did actually attempt to infect the allied armies with plague or that the bacteriological work done in mobile laboratories was not reliable. As I was for four years in charge of a mobile laboratory and for some time actually in the Fifth Army, I wish to make some observations on the meaning of the record in the History of the Great War to which reference has been made.

It is stated that "bacilli resembling the plague bacillus" were found in material dropped from a German balloon, but there is no further record on the subject; this surely means that bacilli resembling the plague bacillus were found and that further investigation showed that they were not identical with the plague bacillus. It is not conceivable that the bacteria found in this material were actually proved to be plague bacilli and that it was considered so trivial a matter that no further notice was taken of it and that the bacteriologists in charge of other mobile laboratories were not even informed about it. Since, however, it would seem that the phrase in the History may be misunderstood it will be as well to analyse briefly its meaning:—

1. The finding of bacteria in material dropped from a German balloon, since bacteria are ubiquitous; this has no significance, unless it is that the material had not been specially sterilised by heat or other means before it was dropped. 2. The resemblance of the bacteria found to plague bacilli; this presumably means that the bacteria belonged to the Pasteurella group, one which includes the plague bacillus as well as many others responsible for diseases of animals and birds which are not transmissible to man.

There were many bacteriologists with the British forces who had had practical experience of isolating the bacillus of plague, but all had not had this experience; especially was this so in the case of those whose experience had been gained in inland towns in Great Britain. A competent observer meeting a problem of this kind for the first time would conclude that with book knowledge only as his guide he was liable to err in differentiating between the plague bacillus and others in the group which resemble it, and therefore rightly render a guarded report. Whether this is the explanation for the cautious report quoted or absence at the time of facilities for experiments by inoculation I do not know; but it is quite clear that the report is merely an indication to the R.A.M.C. authorities responsible that the matter required further investigation. The suggestion that the bacilli found might be plague bacilli, standing as it does without confirmation, has no significance at all.

It is unfortunate that this particular passage in the History of the Great War should have been picked out for so much publicity.

I am, Sir, yours faithfully,
Leeds, April 14th, 1929. JAMES WALTER MCLEOD.

AN OVERDOSE OF THALLIUM ACETATE.

To the Editor of THE LANCET.

SIR,—There have been so many mistakes and discrepancies in the press reports of the inquest on the three boys, who died from an overdose of thallium acetate, that I would like to state the plain facts of the case.

The strength of the solution should have been 7·8 mg. per fluid drachm, and was based on a prescription handed to the hospital dispenser about two years ago. The prescription was written in the Hospital Pharmacopœia and it has always been understood that the solution sent up from the dispensary would be that strength. Acting on this assumption, the correct volume of the medicine was measured out so that each child should receive a dose of 8·5 mg. per kilo of body-weight. Unfortunately the solution was not correct, a decimal point had been misplaced, and each child received ten times too much. Instead of 8·5 mg. per kilo, 85 mg. per kilo were actually given.

A further point which was not made clear was that, on analysis, the solution from the small bottle "B" was only 5·6 and not 10 times too strong. This is accounted for by the fact that after the children had received their medicine from the larger bottle "A," only about one ounce of the solution was left in the bottle, and on being returned to the dispensary, it was emptied out into the smaller bottle "B," which already contained about one ounce of the solution left over from a previous occasion, and which was, of course, the correct strength.

One further remark I would like to comment on. In one paper I am stated to have admitted that one of the cases to whom I had administered the same medicine had afterwards gone off into a "trance." What I really said was that in all the series of cases we had treated only one reported having slight transient pains, and these did not occur until a week had elapsed after taking the medicine.

I am, Sir, yours faithfully,
J. M. SPENCER SCOVELL, M.D., Ch.B. Edin.
London, W., April 15th, 1929.

BLOOD STANDARDS.

To the Editor of THE LANCET.

SIR,—All clinical pathologists will be glad that attention has been drawn in your columns to the marked variations both in the so-called standard of hæmoglobin content and in the readings of instruments by which this is sought to be determined. Fortunately, however, no experienced pathologist would think either of diagnosing or excluding pernicious anæmia on the colour, index alone—that is, without a careful histological examination of stained films and an estimation of the comparative size of the red cells.

Still, in secondary anæmia, especially where repeated estimations of hæmoglobin are required with a view to determining the effect of treatment, the variation in the standards is much too high. This point has troubled me for some years. The Dare instrument is so steeply graduated as to make a high personal error almost inevitable, and it has the grave disadvantage that it is useless when the hæmoglobin reading is very low. The various dilution methods (Sahli, Haldane, and so forth) are, as Dr. Jenkins points out, set to an arbitrary and variable standard. I have, however, found the Tallquist scale useful, provided that the effect of tint (as opposed to tone) is excluded by making the reading monochromatic. For this purpose a piece of pale green glass is sufficient. Both the variations in the colour perception of different observers and the differences in tint between old and fresh supplies of blood are thereby excluded. I have had before me three Tallquist scales of German, Italian, and alleged British origin respectively, which differ very much in colour, and there is evidently no uniformity in this respect amongst the products of different firms. When read through a green glass, however, the difference is not sufficiently great to invalidate the method for clinical purposes.

The subject of hæmoglobin values was discussed at length in the proceedings of the weekly staff meetings of the Mayo Clinic (Sept. 15th, 1926), when the Dare and dilution methods were controlled by spectrophotometric determinations and by the Van Slyke oxygen capacity test. The variations disclosed were enormous. It is to be hoped that work on the lines of the Mayo Clinic procedure may result in the production of an accepted hæmoglobin standard and an accurate method for its determination. Till then I submit that the Tallquist scale with a neutral tint reading is the best that can be employed in clinical practice.

I am, Sir, yours faithfully,
A. KNYVETT GORDON.

Bedford-square, W.C., April 15th, 1929.

PULMONARY NEOPLASMS.

To the Editor of THE LANCET.

SIR,—Dr. T. C. Hunt's paper on this subject in your last issue contains many points of interest, especially concerning the initial symptomatology and diagnosis of the primary carcinoma of the lung.

In an investigation of 62 cases particular attention was paid to the clinical pathology of 29 which came under observation at the Royal Chest Hospital, and the findings seem to show that the negative results invariably reported in the literature are due to insufficiently thorough examination. Cough and pain are early and cardinal symptoms of the disease, and the sputum or pleural fluid (which is nearly always the cause of the first pain) is worth investigation. Blood in the sputum is much more common than the text-books allow, but it may only occur intermittently or in small quantities, and is probably often omitted from hospital records. Specimens examined microscopically at the Royal Chest Hospital have been found to contain blood which was invisible to the naked eye. At this hospital 18 patients had hæmorrhagic sputum; 5 had little or no expectoration, leaving only 6 with no note of bleeding. The presence of carcinoma cells is of some interest in clinching a clinical diagnosis. Very rarely a fragment of growth is coughed up and available for section. One patient here did this three times and on one occasion the piece was large enough nearly to choke her. Isolated malignant cells are always difficult to identify, but after having studied the sputum in a few cases of pulmonary carcinoma, I think that with more experience they will be recognised more frequently than heretofore. In two recent cases the examination of the sputum revealed carcinoma cells while the clinical diagnosis was still doubtful. The procedure is simple and takes no longer than looking for tubercle bacilli in a series of specimens. Search must be made on several occasions and at least two portions of the same specimen examined. I simply make a wet preparation stained with thionin blue and examine at once. The observations are too few to enlarge at present on the nature of the cells and naturally many controls are necessary.

Dr. Hunt refers to the frequency of pleurisy as a complication of pulmonary tumours, but his figures do not bring out the fact that it is a *constant* feature of the condition; they presumably refer to the clinical diagnosis and not to the total incidence as revealed post mortem. Out of 20 post-mortems at the Royal Chest Hospital every case showed extensive pleural adhesions. In 13 there was also a large effusion of clear or cloudy fluid; in 4 the fluid was hæmorrhagic, in 5 it was purulent, and in 8 there was invasion of the pleura by new growth.

I have not found that the large cell sometimes called "foulis" is pathognomonic of pulmonary tumour. The same pale vacuolated cell is found in other forms of pleural effusion and it has no resemblance to the malignant cells obtained if a pleural nodule is scraped. The only certain test of carcinoma in pleural fluid is the presence of columnar or spindle cells, and this is uncommon. Binucleate cells or plaques of endothelial cells forming rosettes indicate a lesion of the pleura not necessarily malignant, and are found in inflammatory conditions. A hæmorrhagic fluid is very suggestive of carcinoma but occurs in only about a quarter of the cases and the diagnosis cannot depend upon its presence.

I am, Sir, yours faithfully,
NORAH H. SCHUSTER, M.B., Ch.B.

Royal Chest Hospital, City-road, E.C., April 15th, 1929.

THE ÆTIOLOGY OF UROLITHIASIS.

To the Editor of THE LANCET.

SIR,—Having read with interest Dr. Clifford Hoyle's instructive article in your issue of April 6th (p. 734) I think his suggestion as to the ætiology of urolithiasis in tropical countries is based on a fallacy. It appears to me that Europeans in the tropics suffer through over-protection from ultra-violet rays. Most of the solar radiation is absorbed in the clothing, where it is converted into heat and conducted to the body with enervating effect, the skin beneath remaining absolutely white. Fear of insolation leads to the covering of the head and shading of the face, so that the majority of the Europeans have pale faces. Urolithiasis in the tropics appears to me likely to be the result of excessive sweating and therefore high concentration of the urine. In any case, when we consider that two ounces of cholesterol contain only one grain of ergosterol it is hardly conceivable that a toxic dose of vitamin D could arise from the irradiation of the face and hands alone.

I am, Sir, yours faithfully,
G. MURRAY LEVICK.

Harley-street, W., April 15th, 1929.

ACTIVE IMMUNISATION AND DIPHTHERIA.

To the Editor of THE LANCET.

SIR,—Dr. Goodall expresses the opinion that the suspicious cases of "local diphtheria," referred to in our paper, should have been counted as cases arising in 1928 subsequent to prophylactic inoculation. His letter is evidence that these cases should have been included, since it was politic to avoid any "attempt to gloss over a failure." Our phrase "suggested a diagnosis" is admittedly unsatisfactory since, when used by an expert of Dr. Goodall's unrivalled experience, it conveys a much higher probability that the patient is suffering from the clinical entity "suggested," than when used by someone with only the same amount of experience as (say) myself.

The subject of the diagnosis of these doubtful cases is of great scientific interest, but much too lengthy to discuss here. I hope my attitude with regard to them will be more intelligible when the full report of this Greenwich work is published. Dr. Goodall asks: Would these local cases, which were excluded from the 1928 diphtheria notifications, have been notified if they had arisen in unimmunised boys? Prior to 1922 the answer is, Yes. Since that date, as more and more confidence was gained in the reliability of the Schick test, both as a diagnostic and prognostic instrument, it has gradually become the local custom, for practical purposes, not to diagnose doubtful cases with no marked malaise and negative Schick tests as diphtheria, even in cases where virulent *C. diphtheriæ* are demonstrated on culture. This is the best routine for the special environment in question, even should its biological basis be proved unsound. Since the school was immunised, only the two cases Dr. Goodall mentions come into this category, and I do not think that they were either severe enough or numerous enough to vitiate the conclusions which were reached on the value of the alleged prophylactic inoculations. A further three and a half months have passed since the report under discussion was written, and no other definite, doubtful, or "local" types of diphtheria have come under observation.

Dr. May and I are grateful to Dr. Goodall for putting his finger on the weak spot in our paper, considered as propaganda, but it is difficult always to avoid making dogmatic statements or expressing unorthodox opinions in a preliminary note on a complex investigation.

I am, Sir, yours faithfully,
SHELDON F. DUDLEY.
R.N. College, Greenwich, April 13th, 1929.

URÆMIA SIMULATING ACUTE INTESTINAL OBSTRUCTION.

To the Editor of THE LANCET.

SIR,—An account of a case of uræmia simulating acute intestinal obstruction was given in your issue of Jan. 19th (p. 128) by Dr. Leslie Cole. The more carefully I read through it the more I thought the case to be rather one of intestinal obstruction simulating uræmia. Again in your issue of Feb. 23rd (p. 416) under the same heading Dr. Leslie Smith and Mr. Kenneth Heritage described a case of definite organic obstruction of the bowel with symptoms of uræmia—namely, coma and abnormal increase of blood-urea. Dr. Cole's case had only impacted fæces obstructing the bowel without any kink, band, or the like, and regular catheterisation led to the fall of urea content of blood. With the exception of this and of the high urea content there was hardly any sign of uræmia; the high urea content could easily be explained by the intestinal obstruction without entertaining the hypothesis of uræmia, and the fall of urea attributed to catheterisation might have taken place without it. Both these are clearly cases of intestinal obstruction with some symptoms (if at all) of uræmia and not uræmia with symptoms of obstruction of the gut, as the heading would have us believe.

An interesting suggestion is made by Dr. Smith and Mr. Heritage that the increase in the blood-urea is due to active hyperfunction of the liver resulting in the formation of a larger amount of urea from the toxic intermediate products of proteids absorbed from the obstructed gut, but in pyloric obstruction with vomiting blood-urea may increase, obviously without such absorption taking place to explain the hyperfunction, and the formation of the larger amount of urea. A more plausible explanation which I have read somewhere would be that in prolonged vomiting or in intestinal obstruction there is less water absorbed, resulting in increased concentration of urea in the blood. This theory is only more plausible than that of liver hyperfunction, but not very satisfactory. To accept it means to pronounce discredit to the healthy kidneys' capacity to maintain the composition of blood, in conditions of lessened water absorption from the gut, by secreting a smaller quantity of concentrated urine, which allows urea to pass out and retains more water in the blood, preventing increased concentration of the urea in it.

Beaumont and Dodds, in "Recent Advances in Medicine," mention the occurrence of nitrogen retention in the blood in certain abdominal conditions, and also suggest the simple and efficient means of diagnosis of such condition from renal defect causing nitrogen retention by estimating urea in urine. In neither of the cases of uræmia simulating intestinal obstruction the urea of the urine seems to have been estimated which might otherwise have shown the raised blood-urea to be due to some extrarenal cause. Beaumont and Dodds, however, do not, as far as I know, point out in that book the cause of nitrogen retention in the abdominal conditions. I wish they could be induced to let us know what they think best explains the high blood-urea figure in intestinal obstruction or other acute abdominal condition.

THE DANGEROUS DRUGS REGULATIONS.

To the Editor of THE LANCET.

SIR,—The recent case in the coroner's court in which a motor-bus driver caused the death of two pedestrians owing to a temporary feeling of dizziness while he was at the wheel, forcibly draws attention to the stupidity of the present regulations under the Dangerous Drugs Acts. The driver confessed to having taken 28 drops of chlorodyne on an empty stomach to cure a cold and lost control of his vehicle while under the influence of the drug.

There can be few members of the medical profession who have not found the recent regulations with regard to heroin and cocaine when prescribed, even in the minutest of doses, both annoying and vexatious, and it seems astonishing that morphia should not have been included. If we are to write elaborate prescriptions for the quite irrecoverable amounts of heroin in the simple cough mixtures, linctuses, and lozenges that have given relief for so many years, it seems stupid that we are not bound to do so for the more dangerous drug morphia. That this is a sop to the patent medicine trade is quite obvious, but, at the same time, when morphia in the form of chlorodyne can be bought freely and be taken in sufficiently large doses by the general public as to endanger the lives of others, it is time equally drastic regulations were made for its use.

Most chemists know of customers who come frequently to buy chlorodyne in quantities far above their normal requirements, and there is no doubt that it is abused by morphiomaniacs. Several of my patients who for years had been getting simple heroin or cocaine lozenges and found that these prescriptions were useless after Jan. 1st, expressed the opinion that these regulations were made by the medical profession in order to obtain more consultations. The injustice of the accusation was palpable but difficult to explain away when one of them pointed out that it is still possible to obtain opium-bearing medicines without a prescription.

C. BERKELEY WAY, M.B., B.S. Lond.
Finchley-road, N.W., April 13th, 1929.

CIVIC PRESENTATION TO A MEDICAL MAN.—Lieut.-Colonel Edwin Goodall, medical superintendent of the Whitchurch Mental Hospital, Cardiff, was presented by the Lord Mayor of that city, Alderman W. R. Williams, on April 8th, with an illuminated address from the council on his retirement after 23 years' service. Tributes to the good work which Dr. Goodall had done at the mental hospital were made by several members of the council and the appreciation of the corporation and citizens was emphasised. Mention was made of the fact that when Dr. Goodall was medical superintendent of the Joint Counties Asylum at Carmarthen he had mastered the Welsh language in order to be able to get into closer touch with Welsh patients. In his reply the recipient expressed his pride in being so long associated with a city that had been progressive enough to anticipate coming changes in organisation for the treatment of mental disease by establishing an out-patient clinic in connexion with the Royal Infirmary, while provision had been made for a department of nervous and mental diseases at the hospital now being erected at Llandough. Dr. Goodall and his colleague, Dr. H. A. Scholberg, were afterwards the guests of the Lord Mayor at luncheon in the City Hall.

Public Health Services.

AN OUTBREAK OF IMPORTED SMALL-POX.

A SEVERE type of small-pox has reached this country by sea from India. On March 27th a seaman was landed at Marseilles from an Anchor Line steamship and died the same day from small-pox which had not, it is stated, been recognised as such up to the time he was admitted to the French hospital. The steamship was the *Tuscania* which left Bombay on March 14th, after a stay of a week or more in that port, with a total complement of nearly 1000. Some 200 of the passengers left the liner at Marseilles on March 27th and travelled direct to London or elsewhere, the majority remaining on board as far as Liverpool. The seaman who was landed and died at Marseilles had, it appears, been ill from March 17th, and on March 18th another member of the crew fell ill but was not landed at Marseilles. On arrival at Liverpool, however, on April 1st he was removed to hospital along with several contacts. As soon as possible after leaving Marseilles every person on board (including about 200 children) was vaccinated, or revaccinated, with the least possible delay. On reaching Liverpool some 650 passengers disembarked, information being sent by the port authorities to the districts to which they were stated to be proceeding. Several passengers subsequently proceeded on the vessel to Glasgow, where the crew were disembarked. The authorities at Liverpool also informed the local authorities of the destination (as far as known) of the 200 persons who left the ship at Marseilles and travelled overland.

The Ministry of Health states that the central and local health departments in this country are proceeding on the customary lines in regard to notification, isolation, and disinfection, keeping contacts as far as possible under supervision. It was, however, anticipated that a number of secondary cases would occur in persons who had not been adequately vaccinated before their contact with the infection. Up to the time the official statement was issued on Saturday last some 35 cases of this imported infection were notified in London and elsewhere, among whom five deaths occurred. Later reports indicate that two more members of the crew fell ill in Glasgow, one seriously, and a mild case of small-pox was reported from Keighley in a member of the ship's orchestra. No fresh case among the *Tuscania* contacts has been reported to the Metropolitan Asylums Board this week. As we go to press the figures stand at 42 secondary cases with 6 deaths.

A GUIDE TO MEDICAL INSURANCE PRACTICE.

MEDICAL insurance practice has a tendency to grow more and more complicated as the years go by; with amending Acts and new regulations the maze thickens, and there is a correspondingly greater need for elucidation and guidance of the insurance practitioner. It might be just possible for him to sort them out from a mass of papers issued by the Ministry of Health through the Stationery Office, but this unfruitful labour has been rendered superfluous by the combined work of a (late) assistant secretary in the Ministry and a barrister-at-law. The first edition of "Medical Insurance Practice," by Mr. R. W. Harris and Mr. L. Shoeten Sack, appeared six years ago,[1] and received immediate acceptance as a compendium at once authoritative and readable. The third edition, which has just been issued by the British Medical Association (price 3*s*.), and has received the approval of the National Insurance Defence Trust, has been brought fully up to date in matter and format. The first three chapters deal with the relationship of the insurance practitioner to the insurance committee on the one hand, and the insured person on the other; marginal references to later chapters furnish a ready means of reference to points of difficulty as they may arise. Next are set out the practitioner's duties towards insured persons who are on other doctors' lists or who have not chosen a doctor at all. The definitions of sudden emergency and availability are discussed at useful length. The next chapter explains how the list of insured persons for whom a practitioner is responsible is limited to a certain number fixed by the allocation subcommittee. Then follow the responsibilities and duties of deputies, and assistants and partners. Chapter VII. reviews the range of general practitioner treatment; decisions are quoted on cases regarded as within/without the scope of medical benefit. The obligation to visit and the providing of anæsthetics is gone into well and fully; the cases in which a fee may/may not be charged are defined. The question of prescribing leads on to the compilation of the National Formulary. A whole chapter is devoted to the difficult question of certification, examples being given of the irregularities which have been dealt with in official decisions. The record cards are described, and their purpose is clearly shown in a separate section. An important chapter is devoted to the regional scheme and the relations of practitioners to the regional medical officers. The basis of remuneration is fully explained, with the constitution of the various funds. The investigation of complaints, and the method of appeal to the Minister is next dealt with, and finally the disciplinary action which may be taken by the Minister is described. In addition, there are many valuable appendices.

The book, as we noted on its first appearance, makes a pleasant appeal to the medical reader by addressing him or her in the second person, and when emphasis is needed it is laid by means of black type more elegant than the italics of former editions. The conversational style conceals, but does not impair, the legal precision of what may be regarded as an essential guide for the insurance practitioner in the proper conduct of his practice.

INFECTIOUS DISEASE IN ENGLAND AND WALES DURING THE WEEK ENDED APRIL 6TH, 1929.

Notifications.—The following cases of infectious disease were notified during the week:—Small-pox, 273 (last week 323); scarlet fever, 1801; diphtheria, 1011; enteric fever, 43; pneumonia, 2158 (last week 2425); puerperal fever, 34; puerperal pyrexia, 112; cerebro-spinal fever, 13; acute poliomyelitis, 7; acute polio-encephalitis, 1; encephalitis lethargica, 24; dysentery, 6; ophthalmia neonatorum, 88. No case of cholera, plague, or typhus fever was notified during the week.

The number of cases in the Infectious Hospitals of the Metropolitan Asylums Board on April 9th–10th was as follows: Small-pox, 162 under treatment, 10 under observation (last week 163 and 0 respectively); scarlet fever, 1554; diphtheria, 1795; enteric fever, 12; measles, 96; whooping-cough, 1209; puerperal fever, 24 (plus 6 babies); encephalitis lethargica, 81; poliomyelitis, 4; "other diseases," 61. At St. Margaret's Hospital there were 12 babies (plus 7 mothers) with ophthalmia neonatorum.

Deaths.—In the aggregate of great towns, including London, there was 1 death from small-pox, 2 (0) from enteric fever, 56 (3) from measles, 5 (1) from scarlet fever, 154 (54) from whooping-cough, 29 (5) from diphtheria, 57 (16) from diarrhœa and enteritis under two years, and 328 (48) from influenza.

The death provisionally classified to small-pox was assigned to West Ham. Great towns reporting ten or more deaths from influenza were Birmingham, 21; Bradford and Sheffield, 10 each. Birmingham and Liverpool each reported 10 deaths from measles, West Bromwich 7. Whooping-cough deaths are still widely distributed, with the highest figures reported from Birmingham, 11; Manchester, 8; Liverpool, 7; West Ham and Hull, each 6. No great town reported more than 5 deaths from diarrhœa, Manchester alone having as many.

The number of stillbirths reported during the week was 296 (corresponding to a rate of 44 per 1000 births), including 45 in London.

---

[1] See THE LANCET, 1922, ii., 982.

THE SUPPLY OF RADIUM.

OFFICIAL PROPOSALS AND RECOMMENDATIONS.

THE Report[1] of the Radium Subcommittee of the Committee of Civil Research, appointed in July, 1928, has now been issued. The subcommittee, which was charged to examine the radium requirements of Great Britain in relation to the present sources of supply and to submit recommendations, consisted of the following persons :—

Lord Rayleigh (chairman); Sir Sydney Chapman, Chief Economic Adviser to H.M. Government; Mr. H. L. F. Fraser, Assistant Secretary, Department of Health for Scotland; Sir Walter Fletcher, Secretary, Medical Research Council; Lieutenant-General Sir Webb Gillman, Master-General of the Ordnance, War Office; Mr. J. F. N. Green, Assistant Secretary, Colonial Office; Mr. M. Heseltine, Assistant Secretary, Ministry of Health; Sir Thomas Holland, Director, Geological Survey of India, 1903–1909; Sir George Newman, Chief Medical Officer, Ministry of Health; Sir Robert Robertson, Government Chemist; Sir Ernest Rutherford, President of the Royal Society; Mr. H. T. Tizard, Secretary, Department of Scientific and Industrial Research; with Mr. A. F. Hemming (Assistant Secretary to the Committee of Civil Research), as Secretary.

The Report starts with a clear summary of the position to which radium has now attained in medical treatment, the conclusion being come to that the best radium practice in Great Britain is now as good as that in any country. This view is substantiated by a reference to the technical methods elaborated for the treatment of cancer by radium in almost every region of the body except the stomach, and adopted for application either in greatly improved ways or following new devices. "Of the various forms of cancer," the Report here runs, "for which radium has been tried, none affords a more striking example than cancer of the womb." The number of women who died of this form of cancer in 1926 is quoted as 4409, and, says the Report, "there can be little doubt that if there had existed an adequate supply of radium in this country available for medical treatment, the lives of many of these women might have been prolonged, and much suffering avoided."

Supply and Demand.

The Report goes on to analyse the existing supply of radium available for treatment in Great Britain and the methods adopted for its distribution. The Medical Research Council hold the equivalent of approximately 2·4 grammes of radium element, the bulk of which is distributed on loan to hospitals which have submitted approved schemes of research, a fraction only being allocated for purposes of experiment. An important fraction is retained centrally at the Middlesex Hospital as a source of supply of radium emanation (radon), the expenses of this radon centre being defrayed by a grant from the British Empire Cancer Campaign. An estimate is added of the amount of radium possessed by other institutions than those subsidised by the Medical Research Council and by private practitioners, and of the private radium stock in Scotland. It is shown, then, that the total available from all sources in Great Britain is approximately 24·9 grammes, of which 22·7 grammes are distributed unevenly over England and Wales, and 2·2 grammes are held in Scotland. The estimated need for the country is 50 grammes.

The sources of radium production in the world are stated with a caution as to the difficulty of making a trustworthy estimate; at the present time very little radium is being produced anywhere except in Belgium where the Belgian Congo ore is treated.

The attempt to arrive at the cost of production placed before the Subcommittee some very complex problems, and as the existence of new sources become indicated, in the British Empire and elsewhere, it may be possible to produce radium later in commercial quantities at an economic price. But time must elapse before this contingency arises, and in the meanwhile any considerable addition to the stock of radium available for medical purposes in this country will have to be derived from the Belgian producers. For this object a body of National Trustees will be appointed (see below), and it is suggested that if purchases can be made through a single agency it might be possible to buy at a substantially lower figure than the present retail price of £12 a milligramme.

Summary of Conclusions.

The Subcommittee summarise their conclusions as follows :—

(1) Knowledge of the biological and curative properties of radium for the treatment of cancer and of the technique of its application has advanced very rapidly in recent years and has greatly increased, and is likely still further to increase, the amount of radium required for medical purposes in Great Britain.

(2) The amount of radium belonging to the Government which is available for medical purposes in England, Scotland and Wales is 2·2 grammes, and the estimated amount believed to be the property of hospitals and private medical practitioners, or likely so to be in (say) three months' time, is approximately 22·7 grammes, making a total of 24·9 (or say 25) grammes.

(3) The amount required to meet existing needs in Great Britain is probably approximately 49 or 50 grammes—i.e., an immediate addition of about 24 grammes to the existing national stock is required.

(4) Owing to the lack of trained personnel and to the inadequacy of the available hospital accommodation it is probable that not more than 20 additional grammes of radium could be effectively absorbed for medical purposes by the end of 1930.

(5) Full advantage can be obtained from a given quantity of radium only when it is constantly in application—i.e., when it can be transferred from one patient to another with a minimum of delay. Such conditions are only to be found in centres possessing the necessary specialist personnel, technical equipment, and available beds.

(6) There is at present no common policy between the hospitals in acquiring radium, hospitals buying such quantities as the resources at their disposal or local munificence render possible, with the result that existing private stocks of radium have been acquired for particular localities without reference to the needs of the country as a whole.

(7) There exists a pressing need for the establishment of a central stock of radium and the organisation of some systematic method for its distribution.

(8) Until sources of supply at present unproved or unknown are discovered in the Empire or elsewhere, the only source from which additional supplies of radium for medical purposes is obtainable in any quantity is the Belgian Congo.

(9) If an organisation such as that referred to in (7) above was established it should be possible for it to obtain radium for substantially less than the existing market price, as it would be in a position to arrange large purchases spread over a considerable period.

(10) Such an organisation should also be given powers not only to purchase radium for its own purposes but also to act, when so requested, as a buying agent for hospitals and other institutions in this country or for Dominion or Colonial Governments.

(11) The amount of radium required by the Government for the Fighting Services and for use in physical research is relatively so small that it would be a mistake to require that additional radium needed for these purposes should be bought through the agency of any organisation that may be established for medical purposes.

Recommendations.

In the light of these conclusions, the Subcommittee submit the following recommendations in regard to the medical use of radium for the consideration of the Committee of Civil Research :—

(1) Steps should be taken at once to ensure the acquisition by instalments of 20 additional grammes of radium element for medical purposes.

(2) A body of Trustees should be appointed entitled the National Radium Trustees, whose duty it should be to hold the funds provided by Parliament or otherwise, and to purchase therewith and hold radium for use by the Radium Commission referred to in (4) below.

(3) The National Radium Trustees should consist of the following persons :—

The Lord President of the Council, the Minister of Health, the Secretary of State for Scotland, the President of the Royal Society, the President of the Royal College of Physicians of London, the President of the Royal College of Surgeons of England, the Chairman of the Central Liaison

---

[1] H.M. Stationery Office. Cmd. 3303. 6*d*.

Committee of Voluntary Hospitals in Scotland, the President of the Royal Society of Medicine, the President of the British Medical Association, and two members to be coöpted, if subsequently so desired, by the National Radium Trustees.

(4) The National Radium Trustees should appoint a body to be called "The Radium Commission," who should have the following powers and duties :—

Generally to deal with the custody, distribution and use of all radium held by the Trustees, having regard to the advancement of knowledge, the treatment of the sick, and economy of use ; and, in particular, to consider and approve plans submitted to them for the use of radium for the purposes of medical treatment and research, and to make the necessary arrangements for the supply of radium for such uses.

(5) The Radium Commission should consist of the following nine persons :—

(*a*) A Chairman, who should be a distinguished public man, not necessarily a member of the medical profession, nominated by the National Radium Trustees ;

(*b*) Four persons nominated by the National Radium Trustees ;

(*c*) Four representatives nominated one each by the Minister of Health, the Secretary of State for Scotland, the Medical Research Council, and the Department of Scientific and Industrial Research.

(6) Members of the Radium Commission should be appointed for a period not exceeding four years, and should be eligible for reappointment after an interval of one year, the Chairman being eligible for immediate reappointment.

(7) The Radium Commission should make arrangements with the National Physical Laboratory for :—

(*a*) The custody of the radium put at the disposal of the Commission by the National Radium Trustees when such radium is not actually in use for medical purposes ;

(*b*) Its preparation in form for use ;

(*c*) Its recovery from such preparation on return from loan.

HOSPITALS IN THE UNITED STATES OF AMERICA.

A RECORD OF PROGRESS.

TWELVE months ago the American Medical Association, through the hospital number of its *Journal*, published its first list of all the hospitals in the United States which conform to its standards. Through the same medium it has now issued its second list, which shows an addition of 45 to the number of recognised institutions, and a total increased capacity of 39,016 beds and 1350 cots. The essentials for admission to the Register, as laid down by the Association, are few in number, but sufficient to ensure efficiency. Every member of the medical staff and every visiting physician must be a graduate of a reputable medical school, and there must always be a competent physician-pathologist either on the staff or easily accessible, who must keep careful records. Full histories and records of every patient admitted must be kept, and it is required that staff conferences, at least monthly, but preferably weekly, should be held where there are staffs of three or more for consultation upon difficult cases, and discussion of the causes of death in fatal cases. Other essentials are "able management" and a sufficient number of nurses, and no hospital must be conducted for profit. When the list was first compiled 462 hospitals and sanatoriums were excluded because they failed in some serious respect to reach the standard.

There are now in the United States 6852 hospitals of all kinds, and in the last 20 years the number of beds has grown by an annual average of 25,000. The total of beds and cots (called in America "bassinets") is 936,247. This gives one bed for every 270 persons, as compared with one for 340 as recently as 1920. The best proportion of population to beds is in Wisconsin, where it is as high as 154. The most backward State, from the hospital point of view, is South Carolina, with one bed to every 749 persons, but it is explained that all the backward States are rapidly being levelled up. The beds in the 5619 "hospitals for community use" had an average rate of occupancy of 69 per cent. Not the least curious fact that emerges from the mass of statistics compiled by the Council of Medical Education and Hospitals is *the progressive decline in the number of maternity* hospitals which have steadily fallen from 202 in *1923 to 164 in 1928.* The explanation is that the general hospitals are growing in favour for maternity work, and last year rather more than 88 per cent. of all the babies born in hospitals were born in general institutions. This percentage represents nearly three-quarters of a million births. Many institutions definitely classed as maternity hospitals are, however, doing a considerable amount of other work. Very much more than half the total number of beds in the American hospitals are in what are there called "Government" institutions, which means institutions owned or controlled federally, or by States, counties, and cities. In so vast a territory as the United States any considerable provision of hospital facilities by the Central Government is obviously impracticable, and it is therefore natural that hospitals run by States should provide the majority of the beds. But with over 1000 hospitals and more than 114,000 beds, the institutions provided by the various religious bodies make a remarkable showing. These hospitals, however, derive some part of their income from other than their own denominational resources, and are consequently unable to confine their ministrations to adherents to their own forms of faith. For the first time a list is given of hospitals in the territorial possessions of the United States. They number 229, with a capacity of 20,650 beds and cots ; 87 of these hospitals, with 10,884 beds, are in the Philippine Islands.

In a note on the educational functions of the hospitals it is pointed out that since 1914 the number of medical college graduates taking a "general internship," or fifth year in medicine, has almost doubled, while the quality of the training has far outstripped the numerical gain, thanks to the introduction of a regular curriculum of teaching and practice in most of the large general hospitals. This improvement is due to the action of the American Medical Association, which in 1914 took medical education seriously in hand as, later on, it created a definite ethical and professional standard for hospitals of all descriptions.

Parliamentary Intelligence.

NOTES ON CURRENT TOPICS.

THE BUDGET.

The House of Commons reassembled on Monday, April 15th, after the Easter recess. Mr. **CHURCHILL**, the Chancellor of the Exchequer, made his annual Budget statement. In the course of his speech Mr. Churchill announced that the existing duties on tea would be repealed from April 22nd. The railway passenger duty would be repealed as from April 1st last. A reduction of one-fourth from Oct. 1st would be made in the excise duties on liquor retailers' on-licences for spirits, beer, &c., subject to a reduced minimum duty. Off-licence holders are to be free to sell half bottles of spirits. Relief to agricultural property from rating will begin this month instead of in October. Increased licence duties are to be imposed on brewers for sale, distillers, and tobacco manufacturers in order to counteract their relief under the de-rating scheme. The duty of 30s. is to apply to motor-cycles up to 224 lb. weight instead of 200 lb. A reduction from £40 to £35 of duty will be allowed for goods vehicles from 2 to 2½ tons, with rebate of 20 per cent. for those fitted wholly with pneumatic tyres. An extension of telephone call offices is provided for at rural post offices and railway stations. An extra grant of 15 per cent. will be made towards road schemes on which half the workers come from depressed areas.

HOUSE OF COMMONS.

MONDAY, APRIL 15TH.

Small-pox on "Tuscania."

Lieut.-Colonel **FREMANTLE** asked the Minister of Health if he would state the numbers respectively of the crew of the s.s. *Tuscania* on her recent voyage from Bombay to

Liverpool and of the passengers landed; whether al the passengers and crew were under observation; what number of cases of small-pox had occurred amongst them; what was the number and vaccination history of the cases that had died; and whether any cases of small-pox had been notified from contacts with such passengers and crew.—Sir K. WOOD (Parliamentary Secretary to the Ministry of Health) replied: My hon. and gallant friend will have seen the statement on this case issued by my department and published in the newspapers on Saturday, and at present my right hon. friend is not in a position to make any further statement.

Mr. T. JOHNSTON asked the Secretary of State for Scotland whether he was aware that a member of the crew of the s.s. *Tuscania* was discharged at Marseilles; whether subsequently a wireless message was received from Marseilles intimating that the man had died of small-pox; whether on arrival at Liverpool the other members of the crew were taken to hospital for small-pox; whether on arrival at Glasgow, and before fumigation or disinfection of the ship, an engineer along with 23 cases of chickens and seven barrels of ducks were transferred to the s.s. *Caledonia*, which sailed for New York on April 7th; whether the Transport Workers' Union informed the port medical authorities of the transfer of the engineer and the foodstuffs from the infected ship prior to the sailing of the *Caledonia;* why nothing was done to prohibit this proceeding; whether 40 bags of flour had since been transferred from the infected vessel to the s.s. *California*, and whether he was in a position to assure the House that all proper steps were being taken to prevent a spread of the infection.—Sir J. GILMOUR replied: I have been unable, in the time available, to obtain information on the detailed matters referred to in this question. I am, however, making inquiries and will communicate the result to the hon. Member after these have been completed. I am satisfied that all reasonable steps are being taken by the competent authorities in Scotland to deal with the position and to protect the interests of the public.

Mr. Johnston asked whether Dr. MacGregor, who was in charge of the health department in Glasgow, had sent any wireless messages to the *Caledonia*, and what the purport of the messages were?

Sir J. GILMOUR said that that was one of the points he could not answer.

Sir R. THOMAS: Is the right hon. gentleman aware that the best medical supervision in the world is obtainable at the Liverpool Docks?

No reply was given to this question.

White Women and Coloured Seamen a Cardiff.

Sir ROBERT THOMAS asked the Home Secretary whether he had now decided to take action as a result of the facts revealed some months ago in the report of the chief constable of Cardiff regarding the association of white women with Asiatic and coloured seamen in the dock district, and, if so, along what lines.—Lieut.-Colonel Sir V. HENDERSON (Under Secretary to the Home Office) replied: The problem is not a new one, and I do not think that any immediate and complete solution of it is possible. As my right hon. friend indicated in reply to a question on Jan. 28th last, certain possibilities are being investigated, but I should prefer not to specify them at present.

League of Nations and Radium Supplies.

Commander BELLAIRS asked the Minister of Health whether the whole of the report of the research committee on the world's radium supplies would be brought before the League of Nations as a matter of international concern.—Sir KINGSLEY WOOD replied: The report of the subcommittee of the Committee on Civil Research is being published, and the point raised by my hon. and gallant friend will be considered in due course.

Birth- and Death-rates in Bengal.

Mr. DAY asked the Under Secretary of State for India whether he could give the birth- and death-rates for the province of Bengal for the 12 months ended to the last convenient date.—Earl WINTERTON replied: The latest figures available are for the calendar year 1926. The rates for births and deaths registered in the Bengal Presidency, excluding the Chillagong Hill tracts, were 27·44, 24·7 per *mille* respectively. As the result, however, of special inquiries instituted in connexion with the census reports it has been estimated that more than 26 per cent. of births and deaths in the province are unrecorded.

TUESDAY, APRIL 16TH.

Government and Radium Supplies.

Dr. VERNON DAVIES asked the Prime Minister whether he was now in a position to state what action the Government proposed to take on the Report of the Subcommittee of the Committee of Civil Research on Radium.—Mr. CHURCHILL (Chancellor of the Exchequer) replied: In view of the importance of the matter, and the public interest attracted by it, the Government arranged for the immediate publication of the Report. It will be seen that the Report deals with the national requirements for radium in medical treatment, in the fighting services, and for the purposes of physical research, and with the possibilities of developing new sources of supply. Further, in a full statement as to the use of radium in medical treatment, the subcommittee indicate that a great volume of avoidable distress and suffering persists simply because the radium required for the treatment of cancer is not available; and that the acquisition of further supplies should encourage the wider development of the highest skill in its use, and the allocation of more hospital beds to the treatment of suitable cases. The subcommittee express the opinion that in order to meet the requirements of England and Wales, and of Scotland, 20 grammes of radium, in addition to the stocks already available, or likely to be available shortly, for general medical use, should be acquired within a specified period—namely, before the end of 1930. The subcommittee recommend that the necessary sum, estimated at £200,000, should be raised by a public appeal to which the Government should contribute pound for pound within that maximum sum. The subcommittee also propose the setting up of an organisation consisting, first, of a body to hold the funds and purchase and hold the radium; and, secondly, of a body to distribute the radium and secure its full use in the manner best adapted to further the advancement of knowledge and the treatment of the sick. As regards the recommendations of the subcommittee on the subject of the organisation, these have been accepted in principle by the Government, but the precise form of the organisation will remain open to further discussion. The Government have accepted the financial recommendation of the subcommittee, and they will be prepared to contribute from public funds, up to a maximum of £100,000, to the extent of £1 for every £1 of private subscription for the purchase of additional radium. The Government confidently expect that there will be no difficulty in raising, in a very short space of time, the funds necessary to provide this invaluable addition to the national resources for dealing with one of the most formidable maladies known to us.

Mr. MACDONALD asked if the Government had considered the effect of this announcement on the price of radium, and if it proposed to take any steps to safeguard itself in that matter?

Mr. CHURCHILL: I understand that all that is dealt with in the Committee's report. The House is entitled to the Report, and therefore publicity is unavoidable, but I do not apprehend any serious evil consequences.

Commander BELLAIRS asked if the Report dealt with the international aspects of radium and made any recommendation to bring the matter before the League of Nations, especially with regard to the Belgian monopoly?

Mr. CHURCHILL said that he must frankly confess that, like Commander Bellairs, he was looking forward to studying the Report.

Lieut.-Commander KENWORTHY asked if the right hon. gentleman was aware that every time the Government had gone into the market to purchase radium the price had been raised against them, and if he would consider the suggestion of Commander Bellairs and advise the Foreign Office to examine into the matter of international action?

Mr. CHURCHILL said that he understood, though he did not speak with first-hand knowledge, that this matter was fully discussed in the report.

Replying to Dr. VERNON DAVIES, who asked if there would be an opportunity to discuss the report, Mr. CHURCHILL said that it did not seem to him that the House was going to have very much opportunity for discussing very much more.

Sir R. THOMAS asked if the report dealt with the potential supply of radium in Australia.

Mr. CHURCHILL: That is covered by the statement that I have not yet been able to study the Report.

Mr. R. MORRISON asked if it would not be necessary for the Government to have a supplementary estimate.

Mr. CHURCHILL replied that whatever was right and necessary would certainly be done.

Mr. W. THORNE asked what was the approximate cost of an ounce of radium.

Mr. CHURCHILL replied that he was sorry that he did not happen to have that information in his mind.

Mr. THORNE: Is the right hon. gentleman aware that the cost is about £400,000 per ounce?

Government and Slum Clearances.

Captain GARRO-JONES asked the Minister of Health when he intended to announce his promised plans for slum clearances.—Sir KINGSLEY WOOD replied: The Government hope to be able to lay proposals before the House next session.

Drug Smuggling at Welsh Ports.

Sir Robert Thomas asked the Home Secretary whether he had any information indicating that drugs were being smuggled into this country on a large scale through the ports of Cardiff and Swansea.—Lieut.-Colonel Sir V. Henderson (Under Secretary to the Home Office) replied: The answer is in the negative.

Drugs from Russia.

Sir P. Cunliffe-Lister (President of the Board of Trade), replying to Mr. Day, stated that last year the declared value of drugs, medicines, &c., consigned from Russia to the United Kingdom was £294,077.

Medical News.

University of Cambridge.—At recent examinations the following candidates were successful:—

Diplomas in Public Health, Hygiene and Tropical Medicine. *Part I.*—W. J. C. Auld, R. F. Campbell, G. L. Chadha, Katherine M. Douglas, Bessie G. Jemson, B. F. Lewin, A. P. Martin, R. M. Mathew, L. N. Mathur, Isabel D. Patterson, S. W. Savage, A. G. Shanks, and L. R. Sharma.

University of London: *Forthcoming Lectures.*—Three lectures on the Drug-like Actions of Some Food Constituents will be given by Prof. E. Mellanby, F.R.S., at University College, Gower-street, W.C., at 5.15 P.M., on April 29th and 30th, and May 1st.—Prof. A. Brachet, of Brussels, will lecture on Experimental Embryology at University College, at 5.30 P.M., on Tuesday, May 28th, Wednesday, the 29th, and May 31st.—Two lectures on the Physiology of Glycogen will be delivered by Prof. J. J. R. Macleod, F.R.S., at the London Hospital Medical College, at 5.30 P.M., on Thursday, May 16th, and Friday, the 17th.—Two lectures on the Psychology of Dementia are to be given in English by Prof. E. D. Wiersma, of Groningen, at University College, at 5.30 P.M., on Wednesday, May 29th, and the following day.—Six lectures on Special Sense Physiology will be given by Mr. R. J. Lythgoe at University College, at 5 P.M., on Thursdays, May 2nd, 9th, 16th, 23rd, 30th, and June 6th.—Prof. S. J. Cowell will deliver six lectures on Dietetics at St. Thomas's Hospital, at 5 P.M., on Thursdays, May 2nd, 9th, 16th, 23rd, 30th, and June 6th.—Two lectures on Some of the Sequels of Epidemic Encephalitis (Lethargica) will be given by Prof. A. J. Hall at University College, at 4 P.M., on Fridays, May 3rd and 10th. Admission to all these lectures will be free, without ticket.

Applications for grants from the *William Smythe Hughes Medical Research Fund* must be received in proper form between May 1st and June 15th. Further particulars may be had from the Academic Registrar.

A University *Studentship in Physiology* of £100 a year will be awarded to a suitable candidate who applies on or before May 31st.

University College, London.—The annual dinner of the Fellows will be held at the College on Tuesday, April 30th, at 7.15 for 7.30, in commemoration of the laying of the first stone of the College buildings by the Duke of Sussex on April 30th, 1827. Prof. F. W. Oliver, F.R.S., who was elected a Fellow in 1886, will preside.

The fund being raised in connexion with the centenary of the College has two main objects—to provide £200,000 for buildings and equipment, and £300,000 for endowment. Rather more than £212,000 has so far been received

University of Leeds.—Three courses of post-graduate lectures will begin on May 1st. Dr. H. W. Davies will lecture on Acidosis, Alkalosis, and Ketosis, at the School of Medicine, Thoresby-place, Leeds, at 3 P.M. on Wednesdays; Mr. A. Richardson will lecture on Emergency Surgery at the General Infirmary on the same day at the same hour; and Prof. W. H. Maxwell Telling will lecture on Diseases of the Ductless Glands at the General Infirmary at 4.30 P.M. on Wednesdays.

A fortnight's general course of clinical instruction and lectures will be given at the General Infirmary and the School of Medicine from July 1st. Details may be had from the Dean of the School of Medicine.

University of Dublin.—The lecturer appointed for this year, Dr. Louis E. J. Werner, will deliver the Mary Louisa Prentice Montgomery Lecture in Ophthalmology in the School of Physic at 5 P.M. on Thursday, April 25th. His subject will be the Slit Lamp in Clinical Practice.—Arrangements have been completed for the holding of the usual three weeks' post-graduate course from Sept. 16th to Oct. 5th. As in former years, as far as possible practitioners attending the course will be able to live in college chambers.—A short course of lectures in anæsthetics will be given this term for medical students in their final year by Dr. T. P. C. Kirkpatrick, the University lecturer in anæsthetics. This course is intended to supplement the theoretical and practical instruction which is given at the clinical hospital.

Royal College of Surgeons of England.—At a quarterly meeting of the Council held on April 11th, Lord Moynihan, President, in the chair, a vote of condolence on the death of Sir Anthony Bowlby, past President and past Member of the Council, was passed.—It was decided to expend Lord Beaverbrook's grant of £1000 upon tissue culture research.—The honorary gold medal of the College was awarded to Sir George Makins in appreciation of his valuable services to the College, more especially in arranging and describing the series of drawings in the Army Medical War Collection.—The Jacksonian prize for 1928 was not awarded, the essay received not being of sufficient merit to justify the award. The subject of the essay for 1930 is the Pathology of Ovarian Cysts and its Bearing on Their Treatment.

The following were elected to the Fellowship as Members of 20 years' standing, viz.: Mr. Comyns Berkeley, obstetric and gynæcological surgeon, Middlesex Hospital; and Prof. W. Blair Bell, obstetric and gynæcological surgeon, Liverpool Royal Infirmary.—The President reported that the vacancy on the Court of Examiners occasioned by the retirement of Sir Cuthbert Wallace, whose term of office has expired, would be filled up at the next meeting of the Council.—The Licence in Dental Surgery was conferred upon Max L. Cooper, Cape and Guy's, who has passed the requisite examinations and has complied with the by-laws of the College.

Fellowship of Medicine and Post-Graduate Medical Association.—The Fellowship will hold its first course of instruction for the M.R.C.P. examination from May 7th to June 28th. This will consist of 16 lectures, each delivered at 8.30 P.M., at 11, Chandos-street, Cavendish-square, W. A detailed syllabus will be sent on application to the secretary of the Fellowship, at 1, Wimpole-street, W. 1. On April 29th a three weeks' course on diseases of the throat, nose and ear will start at the Central London Throat, Nose and Ear Hospital. Beginning on the same date is a month's course in psychological medicine at the Maudsley Hospital. From May 6th to June 1st there will be a course in venereal diseases at the London Lock Hospital, and from May 2nd to June 1st the London School of Dermatology will hold a special course of clinical instruction in the out-patient department, with formal lectures on fixed dates. From May 27th to June 8th an afternoon course, under the direction of Dr. Eric Pritchard, will be held at the Infants Hospital.

The World League for Sexual Reform.—The Third International Congress of the World League for Sexual Reform will be held in London, under the presidency of Dr. August Forel, Mr. Havelock Ellis, and Dr. Magnus Hirschfeld, from Sept. 9th to 13th next. The subjects for discussion are: (1) Marriage and divorce; (2) birth control, abortion, and sterilisation; (3) prevention of venereal disease and prostitution; (4) sex and censorship; while one day's proceedings will be devoted to papers on various subjects which do not come under these headings. The languages of the Congress will be English, French, German, and Esperanto. Those who wish to read papers are requested to notify at once Dr. Norman Haire, the hon. secretary, 127, Harley-street, London, W., and any communications for the sections must reach him not later than July 1st. Subscriptions to the Congress and donations for preliminary expenses will be gratefully received by the hon. treasurer, Mrs. Dora Russell, at Telegraph House, Harting, Petersfield, Hants.

Tavistock-square Clinic for Functional Nervous Disorders.—The annual general meeting will be held in the form of a luncheon at the Hotel Russell, Russell-square, London, W.C., on Monday, May 6th, at 1 o'clock. for 1.10 P.M. Sir Frederick Willis will preside; Dr. H. Crichton Miller, the honorary director, will present a report; and Sir Philip Gibbs will be among the other speakers. Supporters of the Clinic are invited to bring guests to the luncheon, tickets being obtainable from Miss Hollingsworth at the Clinic, 51, Tavistock-square, W.C.1.

Kensington, Fulham, and Chelsea General Hospital.—A dinner will be held at the Mansion House, London, by permission of the Lord Mayor, on Tuesday, April 23rd, having for its object the raising of a fund for the rebuilding of this hospital. The Marquis of Carisbrooke will preside and Dame Madge Kendal will be amongst the speakers. The institution is in urgent need of rebuilding, while the shortage of beds and of accommodation for out-patient treatment is extreme in the neighbourhood. The estimated cost of the rebuilding is £70,000, of which £20,000 has been already subscribed.

Royal College of Physicians of Ireland.—At a meeting of the College on April 5th the following were elected Fellows: Nicholas Marshall Cummins, Robert Constable Cummins, and Robert Elsworth Steen.

Lord Dawson of Penn has promised to distribute the prizes and certificates to students of the London Hospital Medical College on Friday, June 28th.

National Association for the Prevention of Tuberculosis.—The fifteenth annual conference of this Association will be held from Oct. 10th to 12th at Newcastle-upon-Tyne. The Association's address is: 1, Gordon square, London, W.C.1.

Royal Sanitary Institute.—A sessional meeting will be held at 3 P.M. on Friday, April 26th, in the City Hall, Cardiff, when Dr. Ralph Picken and Dr. E. Colston Williams will open a discussion on the New Local Government Act. There will also be discussions on Town Planning and the Proposed Reconstruction of Cardiff Bridge.

Medico-Legal Society.—A meeting of this society will be held at 11, Chandos-street, Cavendish-square, W., at 8.30 P.M., on Thursday, April 25th, when Lord Riddell will read a paper on the Sterilisation of the Unfit. The Earl Russell, Dr. Nathan Raw, Dr. R. A. Gibbons, Dr. W. R. K. Watson, and Dr. T. B. Hyslop will take part in the subsequent discussion.

Dr. Jessie Macgregor Memorial Prize.—An award of this prize, of the value of £75, will be made in July to the applicant who presents the best record of original work in the science of medicine. Such work must not have been published earlier than July, 1926. The prize is open to medical women who are medical graduates of the University of Edinburgh, or who have taken the Triple Qualification, and who before qualification have studied medicine for at least one year in Edinburgh. The successful applicant will later deliver a lecture on the subject of her work. Applications marked "Dr. Jessie Macgregor Prize in Medical Science" must reach the Convener of Trustees, Royal College of Physicians of Edinburgh, not later than May 31st.

Hospital Coöperation.—The Special Committee of King Edward's Fund, which is considering the relations between voluntary hospitals and municipal hospitals under the new Local Government Act, is taking definite steps for the establishment of an organisation in the London area for consultation with the London County Council. The British Hospitals Association is arranging for the creation of similar organisations outside London.

Charing Cross Hospital.—At the annual general court of the governors of this hospital last week it was claimed that it is "still the most economically run hospital in London." It is intended during the year to equip the adjoining premises purchased from the Westminster Ophthalmic Hospital, and the out-patient and casualty departments are being enlarged. It is also hoped shortly to rehouse the whole of the nursing staff, and to provide tennis courts, a garden, and private transport.

King Edward's Hospital Fund for London.—Mr. H. W. Marshall has given to King Edward's Hospital Fund £13,000 Japan 4 per cent. Bonds to be added to the "family fund" inaugurated by him in 1927. In 1927 Mr. Marshall, who had also given the Fund freehold property valued at £12,000, presented the Fund with £10,000 3½ per cent. Conversion Stock, and this was augmented last year by a legacy of £3711 from Miss Elizabeth Marshall, sister of the donor. The "Marshall Fund" is the first "family fund" to be created for the benefit of the King's Fund, and was inaugurated by Mr. Marshall in the hope that others might follow his example.

Royal Westminster Ophthalmic Hospital.—This hospital will hold a festival dinner at the May Fair Hotel on Thursday, May 2nd, in celebration of its transference to the new premises in Broad-street, Holborn. The hospital is now in its 112th year and £50,000 is still required to meet the cost of the new building and its equipment, and the higher cost of maintenance. The number of in-patients is now equal to that of the old hospital, and there are also 14 private rooms for paying patients. Eventually the hospital will accommodate 100 persons requiring beds after operations. A new feature of the hospital is a ward for 12 children. Out-patients from the London area attend at the rate of 40,000 a year, and there are facilities for students of ophthalmology.

British Hospitals Association.—The Prince of Wales has accepted the invitation to become Patron of this Association. His Royal Highness explains that he has done so in the belief that he may encourage friendly coöperation between the Association and the King's Fund, of which he is President.

Infant Mortality in Straits Settlements.—From an official report it appears that in Singapore infant mortality has dropped by one-half since 1911, an improvement mainly attributed to the strides which have been made in antimalarial measures.

Medical Diary.

Information to be included in this column should reach us in proper form on Tuesday, and cannot appear if it reaches us later than the first post on Wednesday morning.

SOCIETIES.

ROYAL SOCIETY OF MEDICINE, 1, Wimpole-street, W.

Monday, April 22nd.—8 P.M., Odontology. Casual Communications: Mr. G. Northcroft: The Migration of a Foreign Body. Mr. G. Thomson: Hyperplasia and Hypoplasia. Mr. E. A. Hardy: A Possible Pitfall in a Purely X Ray Diagnosis of a Fractured Mandible. Paper: Mr. Sheldon Friel: The Relation of Function to the Size and Form of the Jaws.

Tuesday,—5 P.M., Medicine. Short papers: Dr. O. Leyton: How Can We Decide Whether a Case of Glycosuria Should be Treated? Dr. W. T. Munro: Pulmonary Tuberculosis Due to Bovine Tubercle Bacilli. Discussion will follow.

Thursday.—5.30 P.M., Urology. Paper: Dr. P. J. Cammidge: Prostatectomy in Diabetics.

Friday.—5 P.M. (Cases at 4.30 P.M.). Disease in Children. 8 P.M., Epidemiology. Paper: Dr. J. Gordon Thomson: Endemic Malaria in Southern Rhodesia.

LECTURES, ADDRESSES, DEMONSTRATIONS, &c.

FELLOWSHIP OF MEDICINE AND POST-GRADUATE MEDICAL ASSOCIATION, 1, Wimpole-street, London, W.

Monday, April 22nd, to Saturday, April 27th.—Queen Mary's Hospital, Stratford, E. Wed., at 2 P.M., Antenatal Demonstration by Mr. L. C. Rivett.—St. John's Hospital for Diseases of the Skin, Leicester-square, W.C. Thurs., at 2 P.M., O.P. Demonstration by Dr. W. K. Sibley. The above are free.—London School of Hygiene and Tropical Medicine, Endsleigh-gardens, W.C. Tues. and Thurs., at 2 P.M., Lecture-demonstration.—Royal Free Hospital, Gray's Inn-road, W.C. Wed., at 5.15 P.M., Lecture-demonstration.—Royal Waterloo Hospital, Waterloo-road, S.E. Special Course in Medicine, Surgery, and Gynæcology.—West End Hospital for Nervous Diseases, Welbeck-street, W. Daily, at 5 P.M., Lecture-demonstrations illustrated by cases. Further information from the Fellowship of Medicine.

NORTH-EAST LONDON POST-GRADUATE COLLEGE, Prince of Wales's General Hospital, Tottenham, N.

Monday, April 22nd.—2.30 to 5 P.M.: Medical, Surgical, and Gynæcological Clinics. Operations.

Tuesday.—2.30 to 5 P.M.: Medical, Surgical, Throat, Nose and Ear Clinics. Operations.

Wednesday.—2.30 to 5 P.M.: Medical, Skin, and Eye Clinics. Operations.

Thursday.—11.30 A.M.: Dental Clinics. 2.30 to 5 P.M.: Medical, Surgical, and Ear, Nose and Ear, Nose and Throat Clinics. Operations.

Friday.—10.30 A.M.: Throat, Nose and Ear Clinics. 2.30 to 5 P.M., Surgical, Medical, and Children's Diseases Clinics. Operations.

ROYAL NORTHERN HOSPITAL, Holloway-road, N.

Tuesday, April 23rd.—3.15 P.M., Dr. E. H. Shaw: Tumours.

ST. JOHN'S HOSPITAL DERMATOLOGICAL SOCIETY.

Wednesday, April 24th.—4 P.M. (at St. John's Hospital, 49, Leicester-square, W.C.), Clinical Cases. 5 P.M., Dr. Roxburgh will open a discussion on Alopecia Areata.

CENTRAL LONDON THROAT, NOSE, AND EAR HOSPITAL.

Monday, April 22nd.—1.30 P.M., Hearing Tests.

Wednesday.—1.30 P.M., Examination of the Larynx.

Friday.—1.30 P.M., Examination of the Mouth and Pharynx. 4 P.M., Mr. H. Kisch: Frontal Sinus Operations.

ROYAL DENTAL HOSPITAL POST-GRADUATE LECTURES.

Wednesday, April 24th.—6 P.M., Prof. J. C. Drummond: Certain Biochemical Aspects of Saliva.

EUGENICS SOCIETY, at Burlington House, Piccadilly.

Wednesday, April 24th.—5.15 P.M., Mr. C. J. Bond: Hæmolateral Asymmetry in Animals and Man, and its Relation to Cross-breeding.

CENTRAL ASSOCIATION FOR MENTAL WELFARE, at Central Hall, Westminster.

Thursday, April 25th, and Friday, the 26th, Conference on Mental Welfare.

MANCHESTER ROYAL INFIRMARY POST-GRADUATE COURSE.

Tuesday, April 23rd.—4.15 P.M., Dr. A. H. Holmes: Minor Medical Operations.

Friday.—4.15 P.M., Mr. W. R. Douglas: Demonstration of Surgical Cases.

ANCOATS HOSPITAL POST-GRADUATE LECTURES, Mill-street.

Thursday, April 25th.—4.15 P.M., Mr. E. E. Hughes: Modern Urological Methods.

Appointments.

Lytle, W. J., F.R.C.S. Eng., has been appointed Assistant Surgeon to the Royal Infirmary, Sheffield.

Summers, R. D., L.R.C.P. Lond., M.R.C.S., District Medical Officer for the London County Council, District 12.

Certifying Surgeons under the Factory and Workshop Acts: Harper, C. G., L.R.C.P. Lond., M.R.C.S. (Market Deeping), and Harper, F. G., M.D., Ch.B. Edin. (Somercotes).

Vacancies.

For further information refer to the advertisement columns.

Bath, Royal United Hospital.—H.P. Also Asst. H.S. At rate of £120 and £100 respectively.

Bedford County Hospital.—Asst. H.S. At rate of £130.

Bedfordshire Sanatorium, near Bedford.—Res. Asst. M.O. £150.

Birmingham, Ear and Throat Hospital.—3rd H.S. At rate of £150.

Birmingham General Hospital.—H.P. £70.

Birmingham and Midland Eye Hospital, Church-street.—Surgical Registrar.

Burnley, Victoria Hospital.—H.S. At rate of £125.

Bradford Royal Infirmary.—H.P. and 2 H.S.'s. Each £150. Also Hon. P.

Brighton, Royal Sussex County Hospital.—Three Hon. Med. Clin. Assts. Also Hon. Clin. Asst. to Dental Department.

Bristol Education Committee.—Asst. School M.O. £600.

Bristol Royal Infirmary.—Hon. Med. Reg. Also Hon. Reg. to Ear, Nose and Throat Dept.

Bristol University—Chair of Physiology.

Bury St. Edmund's, West Suffolk General Hospital.—H.S. £150.

Cancer Hospital, Fulham-road, S.W.—H.S. At rate of £100.

Cardiff Royal Infirmary.—Ophthalmic H.S. At rate of £75.

Central London Throat, Nose and Ear Hospital, Gray's Inn-road, W.C.—Second Res. H.S. £75.

Derby, Bretby Hall Orthopædic Hospital, near Burton-on-Trent.—Res. Med. Supt. £750.

Derby, Derbyshire Education Committee.—Asst. School M.O. £600.

Derby Guardians' Institution and Infirmary.—Second Res. M.O. £250.

Edinburgh Royal Infirmary.—Secretary and Treasurer. £900.

Elizabeth Garrett Anderson Hospital, Euston-road.—Jun. Asst. Obstetrician. Also Asst. Radiologist. £100.

Evelina Hospital for Children, Southwark, S.E.—H.S. At rate of £120. Also Hon. Phys. to Out-Patients.

Farringdon General Dispensary, Holborn-circus, E.C.—Physician.

Gravesend and North Kent Hospital.—Jun. H.S. £80–£200

Hackney Hospital, High-street, Homerton, E.—Jun. Asst. M.O. £350.

Halifax Royal Infirmary.—Third H.S. At rate of £100.

Harefield, Middlesex, County (Tuberculosis) Sanatorium.—Third Asst. Res. M.O. £400.

Hôpital Français, 172, Shaftesbury-avenue, W.C.—Jun. Res. M.O. £100.

Hospital of St. John and St. Elizabeth, 60, Grove End-road, N.W.—Res. H.P. At rate of £100.

Hove Hospital, Sackville-road.—Res. M.O. £150.

Hull Royal Infirmary.—Hon. Physician.

Inverness, Northern Infirmary.—Pathologist and Bacteriologist. £700.

Kingston-upon-Hull City and County of.—Asst. M.O.H. £600.

Liverpool Port Sanitary Authority.—Asst. Port M.O. £700.

Liverpool, Royal Liverpool Babies' Hospital, Woolton.—Res. M.O. At rate of £90. Also Locum.

Liverpool, Stanley Hospital.—H.P. At rate of £100.

London Hospital, Whitechapel, E.—Gynæcological First Asst. and Obstetric Tutor. £300.

London Female Lock Hospital, Harrow-road, W.—Hon. Obstet. Surg.

London Temperance Hospital, Hampstead-road, N.W.—Surg. Reg. 40 guineas.

Manchester Royal Infirmary.—First Asst. in Clinical Laboratory £350. Also Dickinson Research Travelling Scholarship in Medicine. £300. Also Pathology Scholarship. £75.

Manchester Victoria Memorial Jewish Hospital.—Hon. Gyn. Surgeon.

Miller General Hospital, Greenwich-road, S.E.—Out-patient Officer. At rate of £150.

New End Hospital, Hampstead, N.W.—Jun. Res. Asst. M.O. At rate of £200.

Norwich City Mental Hospital.—Jun. Asst. M.O. £500.

Plumstead and District Hospital, Plumstead High-street, S.E.—Third Asst. M.O. £300.

Queen Charlotte's Maternity Hospital, Marylebone-road, N.W.—Res. Anæsthetist. £80.

Queen's Hospital for Children, Hackney-road, E.—H.P. and Cas.O. Each at rate of £100. Also Surg. to Ear, Nose and Throat Dept.

Rhondda Urban District Council.—Asst. M.O.H., &c. £600.

Royal National Orthopædic Hospital, 234, Great Portland-street, W. Surgical Registrar. At rate of £105.

St. Albans, Hertfordshire County Mental Hospital.—Pathologist. £525.

St. Bartholomew's Medical College.—Senior Curator of Museum.

St. Helens County Borough.—Asst. M.O.H. £450.

St. Mary's Hospital, Institute of Pathology and Research, Paddington, W.—Research Studentship. At rate of £200.

Samaritan Free Hospital for Women, Marylebone-road, N.W.—H.S. At rate of £100.

Sheffield, Nether Edge Hospital.—H.P. £150.

South Shields, Harton Poor-law Institution, &c.—Res. Asst. M.O. £300.

Sunderland, Royal Infirmary.—Hon. Physician.

Walsall General Hospital.—Jun. H.S. At rate of £100.

West Bromwich and District General Hospital.—Two Hon. Ophth. S.'s. Also Hon. Anæsthetists.

Wolverhampton and Midland Counties Eye Infirmary.—H.S. £200.

Wolverhampton, Royal Hospital.—Res. M.O. At rate of £150.

Woolwich and District War Memorial Hospital, Shooters' Hill, S.E.—H.S. At rate of £125.

The Chief Inspector of Factories announces vacancies for Certifying Factory Surgeons at Norwich (Norfolk); Kingsclere (Hants.); and at Rhayader (Radnorshire).

The Home Secretary gives notice of a vacancy for a Medical Referee under the Workmen's Compensation Act for the District of Barnsley County Court. Applications should reach the Private Secretary, Home Office, Whitehall, London, S.W. 1, not later than May 1st.

Births, Marriages, and Deaths.

BIRTHS.

Ballance.—On April 8th, at Westfield, Hatfield, the wife of Dr. Ballance, of a daughter.

Murray Bligh.—On April 12th, at 74, Rodney-street, Liverpool, to the wife of John Murray Bligh, M.D. Liverp., M.R.C.P. Lond.—a son.

Price.—On April 11th, at the Maternity Home, Driffield, to Dorothy Price, M.B., B.Ch. (*née* Tait), the wife of V. R. Price, of Hornsea, Yorks, of a daughter.

Pye.—On April 10th, at a nursing home in Winchester, the wife of Dr. E. A. Pye, *of a son.*

MARRIAGES.

Bush—Vizard.—On April 13th, at All Saints' Church, Hove, Dr. Frank Parkinson Bush, of Chester-place, Norwich, to "Betty" (Florence), only daughter of Mrs. W. Vizard, of Denmark Villas, *Hove.*

Smellie—Lamsdale.—On April 10th, 1929, at Sutton Coldfield Parish Church, James Maclure Smellie, M.D., M.R.C.P., to Kathleen, only daughter of Mr. and Mrs. H. Lamsdale, of Four Oaks, Sutton Coldfield.

DEATHS.

Addinsell.—On April 8th, at The Old Prebendal House, Shipton-under-Wychwood, Oxon., Lieut.-Colonel Augustus Whitehorn Addinsell, M.R.C.P., aged 71 years.

Kirkwood.—On April 13th, at Tymawr, Ravenslea-road, S.W., Thomas Kirkwood, M.A., M.B., C.M., D.P.H., in his 62nd year.

Rutherfurd.—On April 14th, at Bute-gardens, Glasgow, W., Henry Rutherfurd, M.A., M.B., C.M., F.R.F.P.S. Glasg.

N.B.—A fee of 7s. 6d. is charged for the insertion of Notices of Births, Marriages, and Deaths.

Notes, Comments, and Abstracts.

RELIEF OF LOCAL RATES UNDER THE LOCAL GOVERNMENT ACT.

NINE Conservative Members of Parliament, who have made a special study of the ground covered by the new Local Government Act, have combined to expound its various aspects in a readable little book.[1] Mr. R. S. Hudson's chapter on "Poor Law" is a particularly good summary of the English system of poor relief from Elizabethan times. He cites effectively the list of inmates to be found in one poor-law institution last November—7 acutely sick persons, 9 uncertified mental deficients, 55 infirm and senile, 6 epileptics, 18 certified mental deficients, one able-bodied man, 8 certified lunatics, and 3 healthy infants. Mr. D. W. Gunston, in a chapter on "Rural Areas," makes the same point, and asks whether anyone would be anxious to enter such a place. London is specially dealt with by Sir Cyril Cobb, who describes the negotiations which preceded the agreement upon Mr. Chamberlain's final clauses. Mr. T. J. O'Connor attacks the rival policies of the Labour and Liberal parties, and Mr. Geoffrey Peto sums up at the finish. Though this little volume on "Rating Relief" is mainly concerned with the English legislation, room has fortunately been found for an excellent chapter on Scotland by Mr. C. M. Barclay-Harvey, which not only shows the differences between the two national systems of local government, but also prepares us for the corresponding Scottish Act which Parliament is expected to pass into law during the next few weeks. Both in England and Scotland the changes are so vast that any help towards understanding their general principles is welcome. "Rating Relief" is a sincere and competent contribution.

Sir Kingsley Wood has all the arguments at his fingers' ends, and has marshalled them lucidly and persuasively. His book[2] covers the whole plan of the Local Government Act in some 60 readable pages with an appendix of the figures (already published elsewhere), showing how the Act may be expected to affect the rates in areas in England and Wales. Within the brief limits set for it, "Relief for the Ratepayer" is the best book of its kind, valuable not only to the political advocate on the platform, but also to the army of voluntary administrators whose unselfish devotion to the public service will, as the Minister of Health says, now find new and wider scope for its activity.

A FATAL DRAUGHT OF MEDICINE.

A MAN, aged 39, living at Mayfield, in Sussex, developed a severe cold and sore-throat, and on April 2nd received a prescription from his medical adviser, Dr. G. A. Shackel, and had it made up by the local chemist. He took two or three doses, and about 1 P.M. on April 3rd he swallowed a whole dose in one mouthful, and died in a few minutes. The inquest was opened on April 5th, but the coroner, Dr. E. F. Hoare, adjourned the inquiry in order that the remaining contents of the bottle of medicine might be analysed. On April 9th he announced that the public analyst for East Sussex had written to say that there was nothing poisonous in the medicine which would have caused the patient's death. A nurse who had been called in to attend the patient said she did not know at that time that he had had a drink, or that he was choking. The symptoms, she said, resembled very much those of an epileptic fit, but she knew that he was not in a fit. The convulsions gradually became less, and she applied a mustard leaf without avail. The man did not speak, and died in a few moments. The chemist's assistant who made up the prescription said it was for a diaphoretic mixture containing nothing poisonous. The doses were of the usual strength and the bottle was properly labelled. The directions were further mentioned to the messenger who took the bottle away. Dr. Shackel said that in his opinion death was due to asphyxia caused by the man having choked himself. The heart was in a very weak state and that might have contributed to his sudden death. The man had no doubt choked himself by swallowing a dose of medicine too quickly so that it passed into the windpipe. The coroner said he would return a verdict in accordance with the medical evidence. The case, he added, was rather instructive; the whole point was that the man swallowed the medicine very quickly, and this kind of thing might happen to anyone at any time. He complimented the nurse on her conduct, remarking that no blame attached to anyone.

MEDIÆVAL WILLS.

To the Editor of THE LANCET.

SIR,—In the article on the above subject in THE LANCET for April 6th mention is made of the will of a barber-surgeon of Newcastle dated 1585. In the Surtees Society's publication, *Testamenta Eboracensia*, Vol. I., is the transcription of the will of a barber-surgeon of much earlier date—i.e., Oct. 20th, 1392. This is of considerable interest from the fact that it gives much information as to the furniture and belongings of a barber in the fourteenth century. Therein William de Dalton, who had received his freedom of the City of York as a barber in 1350, directs his body to be buried in the Priory Church of the Holy Trinity, Mykylgat (Micklegate) and bequeaths to the high altar certain linen, wax for candles, and "unam cistam ferro ligatam pro custodiendis ornamentis." Amongst other bequests he bequeaths to his executor Thomas de Garton the instruments of his occupation—viz., j pelvem rotundam parvam, j pecten de ebore, j brusche, j speculum, j cathedram cum sege, unum cochlear novum quod habet in suâ possessione, j razur habens manubrium de ebore."

To his servant Agnes Cuk, he leaves his matrass, and bolster with the bedlinen, his pestle and mortar and the wooden board which was presumably used for spreading ointments, together with the cooking utensils.

From the list of individual bequests it is clear that the testator was very comfortably off and that in his long life he had prospered. He died shortly after making his will, which was proved on March 24th, 1393.

It may be added that in the Church of Holy Trinity, Micklegate, is a mural tablet to Dr. John Burton, the man-midwife, who was the prototype of "Dr. Slop" in Lawrence Sterne's *Tristram Shandy.* A pair of midwifery forceps which belonged to him, and may have been that responsible for the shape of Tristram's nose, is still preserved in the York Medical Library.

I am, Sir, yours faithfully,

Birmingham, April 10th, 1929. G. A. AUDEN.

A FOOLISH MYSTIFICATION.

To the Editor of THE LANCET.

SIR,—The fact, alluded to in a note published recently in THE LANCET, that occasionally an old book gained in value from autograph notes presumably made by a previous owner, was well known to a person in the days when Holywell-street was lined on the south side with books of every description for sale at every price. For a short period a good many book-hunters picked up in Holywell-street for small sums books that were annotated, often with amusing erudition, the entries being made in pencil, and the references occurring in them being now and again to historic circumstances, or to known passages in the lives of public men; several learned bibliophiles, from the internal evidence, were led to believe that they had picked up books which had belonged to the famous dead and, I believe, printed their deductions. It turned out afterwards that the marginal notes were the ingenious labour of a practical joker. He made no profit, as he did not forge the name of any suggested former owner on the title page; thus no Holywell-street shopkeeper was deceived into giving him a high price for an otherwise worthless book—that would have been a difficult accomplishment. Hence the books remained cheap and apparently a prize for such bargain-hunters as made industrious investigations before parting with their pence. The trickster was simply enjoying himself by mystifying book collectors, which he was able to do until the frequency of these curious finds in the book-boxes of Holywell-street led to suspicion and revelation of the trick.

I was told this story, apropos the purchase in a book-box of some work alleged to be annotated by a historic doctor, and my informant professed to know who the silly ass was who was trying to mystify his brother collectors.

Of course, some of these books may have since received value from an acceptance of the forgeries.

I am, Sir, yours faithfully,

April 12th, 1929. M.D.

NEW PREPARATIONS.

Albichthon Ointment.—We have received from the Ichthyol Co., Ltd., 18, Adam-street, Adelphi, London, W.C., a sample of a new preparation of colourless sulphur having the same characteristics as other ichthyol preparations in accordance with its chemical composition, and pharmacological tests justify this view. It contains a little over 12 per cent. of sulphur and is supplied in collapsible tubes of three strengths. Ichthyol, prepared from schist oil obtained from the bituminous shale workings of Seefeld in the Tyrol, has only a slightly lower sulphur content than that of Albichthon, which therefore might be expected to be efficacious in chronic skin diseases such as eczema, psoriasis, and acne, where ichthyol is of a well-tried value that does not require to be insisted upon. The remedy is made up in a convenient way for use.

An Address

ON

ACUTE INTESTINAL OBSTRUCTION.

Delivered before the Medical Society of London on Feb. 25th[*]

By A. H. BURGESS, M.B., M.Sc. Manch., F.R.C.S. Eng.,

SURGEON TO THE MANCHESTER ROYAL INFIRMARY; PROFESSOR OF SURGERY IN THE UNIVERSITY OF MANCHESTER; AND PRESIDENT-ELECT OF THE BRITISH MEDICAL ASSOCIATION.

The acute abdominal crises have always especially interested me, and I am rather concerned to find that it appears to be the custom in London to describe these under the designation "the acute abdomen." I hate that term, and I never hear it without experiencing an almost irresistible desire to immediately confer upon its user an "acute traumatic buttock"—the two terms are about on a parity of inelegance.

Its High Mortality.

The present century has witnessed great improvements in the results of the surgical treatment of abdominal crises, but this improvement has not been obtained equally in the various groups. At the Manchester Royal Infirmary our mortality for acute appendicitis in 1924 was one-twelfth and that for gastro-duodenal perforations one-seventh of that of 1900, whereas that for acute intestinal obstruction was still one-half that of 1900. The best recent series of statistics on acute intestinal obstruction is that which was compiled by Mr. H. S. Souttar for the Bath meeting of the British Medical Association in 1925. He collected the statistics of the five years, 1920–24 inclusive, of seven large hospitals (three in London—Guy's, St. Thomas's, St. Bartholomew's; three in the provinces—Newcastle, Manchester, and Bristol; and the Belfast Royal Infirmary (see table). I hope Mr. Souttar will compile a further series from the same hospitals for the five-year period, 1925–29 inclusive, and present a comparison of the results at Winnipeg in 1930. In adopting Mr. Souttar's figures I wish to modify them by excluding all cases of strangulated hernia and of idiopathic intussusception, my reason being that I wish to-night to consider only those cases of acute intestinal obstruction the diagnosis of which is not readily obvious. There is, nowadays, no excuse for overlooking obstruction from strangulated hernia or intussusception; moreover, the latter is not primarily an obstruction, and, indeed, as pointed out by MacLennan, of Glasgow, the object of early diagnosis and treatment is to prevent an intussusception becoming an obstruction, just as we wish to prevent an acute appendicitis from becoming a peritonitis. Excluding hernia and intussusception, therefore, we are left with 1042 cases with 395 deaths, a mortality of 37·9 per cent.; this is the real mortality of acute intestinal obstruction the cause of which is not readily obvious, and it is this high mortality which we are out to reduce. In Manchester, I am pleased to say, this mortality is tending to diminish; thus at the Royal Infirmary our mortality for the ten-year period 1913 to 1922 was 41·07 per cent., for 1920–24 (the period covered by Mr. Souttar's table) 33·5 per cent., and for 1925 to 1927 (the last year for which we have the reports fully analysed) only 30·2 per cent.

What is the reason for this high mortality? The main reason is delay in the application of surgical treatment. The early diagnosis of acute intestinal obstruction has not kept pace with the improvements in the diagnosis of the other groups of abdominal crises; too many cases still present themselves with distended abdomens and advanced toxæmia. The early signs are not sufficiently insisted upon in the surgical text-books, except the most recent ones, in which, I am pleased to say, there is a decided improvement. Far too much emphasis is usually laid upon fæcal vomiting as a sign of acute obstruction; it should not be regarded as a sign but rather as an end-result. Such emphasis rather encourages the waverer to await fæcal vomiting to complete the clinical picture. The only hand, however, that ever paints a complete pathological and clinical picture of any morbid state is the hand of Death. The man who waits for fæcal vomiting will practically never make a mistake in diagnosis, but rarely, if ever, will he save his patient. Far better for the community in general would it have been had the original advent into this world of such a would-be infallible diagnostician been in itself a perfectly complete clinical picture of the process of stillbirth.

Diagnosis.

Acute intestinal obstruction may be either primary, coming like a "bolt from the blue," or secondary, being engrafted upon the subacute or chronic obstruction. In distinguishing between primary and secondary obstruction there are two important clinical guides. In secondary obstruction we can frequently see (1) the outlines of individual dilated coils, and (2) visible peristalsis passing along them. Sudden acute obstruction always leads to dilatation with thinning of the wall, and is not associated with visible peristalsis. Where the abdominal wall is extremely thin—as in the emaciation following typhoid fever, or in the thinned-out coverings of a ventral hernia, or a divarication of the recti muscle—it may be possible to see visible peristalsis in the absence of any obstruction; but this visible peristalsis is in normal-sized coils and is no exception to the rule that whenever the outlines of individual *dilated* coils can be seen, together with a peristaltic wave passing along them, it is quite safe to diagnose intestinal obstruction of at least several weeks' duration. Even when peristalsis is not visible it may be "palpable"; by keeping the hand flat upon the abdomen the underlying coil may be felt to alternately harden and soften, much like the pregnant uterus.

Primary acute intestinal obstruction varies considerably in its acuteness of onset, being especially acute in internal strangulation, volvulus, and acute intussusception—all conditions in which there is not only an obstruction to the onward passage of the fæcal stream, but also, of much greater importance, to the circulation of the bowel concerned. Fæces may be arrested for days or even weeks but no patient can long survive a complete arrest of the circulation of the bowel. The acuteness of onset depends upon (*a*) the degree of associated strangulation, and (*b*) the site of the obstruction. In general terms the higher the obstruction the more acute the onset, although an exception to this will be recalled in the case of volvulus of the sigmoid colon, the onset of which is extremely acute, probably from the large amount of mesentery involved. The early symptoms of acute primary intestinal obstruction are common to those of any other acute abdominal crisis; they are the symptoms which, years ago, were described by Sir Frederick Treves as "peritonism." They are of reflex origin and have no localising value whatever. In acute intestinal obstruction the pain is always referred to the epigastric region, and I have never known it have any localising value. Often paroxysmal at first, it becomes continuous as the obstruction becomes complete. The vomiting, like the pain, is at first reflex and depends upon the acuteness of onset much more than upon the site of obstruction; later vomiting is due to the mechanical obstruction and appears earlier the higher its site, being most marked in acute dilatation of the stomach (from compression of the third portion of the duodenum) and in gall-stone impaction in the upper jejunum; in low obstruction, as from carcinoma of the rectum, vomiting may be absent throughout. At first the vomit consists of gastric contents, later it becomes bilious, and later still, brown and fæculent in odour, constituting the so-called stercoraceous or fæcal vomit. True fæcal vomit—i.e., the vomiting of actual fæces—never occurs in intestinal obstruction but only in cases of gastro-colic fistulæ (although cases have been recorded as having occurred in functional nervous disease). The persistence of the vomiting is its chief characteristic. The cessation of the passage of fæces and flatus may not be absolute at first, and one, or even two, enemata may bring away fæces present in the bowel below the site of the obstruction. Such does not, however, give any relief to the symptoms.

---

[*] This meeting was reported in The Lancet, March 2nd, p. 441.

Distension of the coil above the site of obstruction must, of course, be present in every case, but it is not always visible. If the case be seen early the distension may be localised, and may prove a valuable guide to the site of obstruction; soon, however, the distension gets uniform and separate coils cannot be distinguished. The degree of distension varies inversely with the vomiting—in high obstruction vomiting is marked with very little distension, in low obstruction the converse obtains. The central distension of small intestine obstruction contrasts with the barrel-shaped abdomen (from distension of the flanks) of sigmoid obstruction. In volvulus of the sigmoid distension comes on extremely rapidly and is intensely marked, the abdomen appearing as if it were about to burst; this distension, be it noted, is in the twisted loop itself and not in the bowel above the volvulus. Steadily progressive abdominal distension is one of the most important signs of intestinal obstruction. Abdominal palpation may sometimes reveal the presence of a tumour in acute intussusception and in malignant disease, and I have twice felt large gall-stones, and in a third case what I took to be a gall-stone, but which proved to be a large hair-ball from the stomach. Auscultation is a much neglected method of investigation, and one to which I attach much value. After a little experience one gets to recognise certain sounds associated with distended intestines, and the contrast between the turbulent gurgling sounds of mechanical obstruction and the deathlike silence of paralytic ileus is very marked.

TABLE ILLUSTRATING MR. H. S. SOUTTAR'S REPORT ON ACUTE INTESTINAL OBSTRUCTION. COMBINED STATISTICS FROM SEVEN HOSPITALS.

Cause.	Age decade.								Site.				Duration in days.					Operation.					Result.		Totals.	Mortality (per cent.).

	Cases.	Deaths.	Mortality (per cent.)
Mortality (excluding hernia and idiopathic intussusception) ..	1042	395	37·9
Mortality of hernia and intussusception combined ..	2022	409	20·22

Rectal examination is of the greatest importance. In some cases the cause of the obstruction itself can be detected, as in stricture or growth of the rectum, or an intussusception may be felt. Sometimes through the anterior wall of the rectum a growth of the sigmoid can be discovered, or the presence of dilated coils of small intestines in the pelvis definitely ascertained. Sometimes "ballooning" of the rectum, so suggestive of sigmoid obstruction, can be felt. Wherever there is any reason to suspect the colon as the site of the obstruction a sigmoidoscopic examination ought to be made. The sigmoidoscope can be passed from 8 to 11 inches, and from a negative point of view it is often valuable to be able to say that there is no obstruction within that distance.

THE SITE AND NATURE OF OBSTRUCTION.

In the absence of any guide, such as a tumour palpable through the abdominal wall, or per rectum, or the presence of a local distension only, the most important step is to distinguish between small and large bowel obstruction. As regards relative frequency Souttar's list (excluding hernia and intussusception) indicate 586 cases of small (57·6 per cent.) to 433 of large (42·4 per cent.) intestine obstruction—that is, the chances are slightly more in favour of small than of large bowel obstruction. The Manchester Royal Infirmary figures show a preponderance of the large bowel, but taking all cases together we may assume that obstruction (excluding hernia and intussusception) is fairly equally divided between the small and the large bowel. A previous medical history of intestinal troubles before the onset of acute obstruction is much more in favour of the large intestine being concerned, since 91 per cent. of obstructions in the colon are due to carcinoma, and this usually produces some previous disturbances, such as colicky pains after meals, often travelling up to and becoming arrested at the same spot, frequently associated with borborygmi, sometimes audible to others, attacks of diarrhœa alternating with constipation, slight attacks of flatulent distension which pass off, and large quantities of mucus in the stools, sometimes even blood-stained. The keynote of the position, however, is the condition of the cæcum—

if this can be seen to be distended or the site of visible peristalsis or, failing this, if palpable peristalsis can be discovered on careful palpation then the obstruction must be in the colon distal to the cæcum.

If the obstruction can be located to the large intestine there is a 91 per cent. chance of its being of a malignant nature—that is, roughly a 9 to 1 chance. On the other hand, if the large intestine can be excluded as the site of the obstruction, then the odds are nearly 300 to 1 against malignancy (out of 586 cases of small intestinal obstruction only two were due to malignant growth); 88 per cent. of small intestine obstructions are due to adhesions or internal strangulations.

TREATMENT.

I refer here only to the treatment of mechanical obstruction, leaving the very interesting subject of post-operative paralytic ileus for consideration by those who follow me. Operative treatment is essential for mechanical obstruction. Accessory forms of treatment may be very useful in conjunction with operation especially—(1) gastric lavage; (2) the introduction of large amounts of hypertonic saline solution subcutaneously or intravenously so as to replace the great loss of fluids and of chlorides from the blood; (3) the administration of antigas-gangrene serum (B. W. Williams); and (4) enemata of bile, as advocated by R. St. L. Brockman, of Sheffield.

The nature of the operation will depend upon the stage of the disease. In *early* cases, with little distension and good general condition, an exploratory laparotomy is undertaken on the usual lines, the only points I would specially stress being the importance of preliminary gastric lavage and the use of spinal anæsthesia (especially Dr. George P. Pitkin's method of controllable spinal anæsthesia). Having discovered the cause of the obstruction, removal, short circuit or artificial anus proximal to the obstruction should be carried out in this order of preference. It is with the *late* cases, with general abdominal distension and poor general condition, that difficulties arise in deciding what is best to be done. With care I think it is possible in most cases to know whether the obstruction is in the large or the small intestine. If it can be located to the colon I feel strongly that one should content oneself for the time being with a blind cæcostomy, carried out under local anæsthesia or under nitrous oxide gas, through a gridiron incision in the right iliac fossa. This will relieve the obstruction. I am well aware that this measure gives one no information as to the exact site or nature of the obstruction, as to the presence of any secondary deposits in the glands, peritoneum or liver, or whether it is capable of removal at some future date, or, failing this, whether short-circuiting is possible. All this information is, of course, essential before the case is finally disposed of; none of it, however, need necessarily be known at the time of the cæcostomy, and it is far better to tide the patient over the immediate necessity (that is, the relief of the obstruction) and not to attempt to acquire this information for the moment. All of it can be much more safely obtained when the obstruction has been removed by cæcostomy. The only serious objection to blind cæcostomy is the risk that the obstruction in the colon may be some form of internal strangulation, so that although the cæcostomy relieves the obstruction the strangulation, not being relieved, would result in perforation and peritonitis. The Manchester Royal Infirmary statistics show that the risk of such strangulation in the colon being overlooked at a blind cæcostomy is at the most 1·5 per cent., and I think even the most optimistic advocate of preliminary exploratory laparotomy must admit that it would add more than 1·5 per cent. to the mortality of blind cæcostomy.

If, however, one cannot, before operation, locate the obstruction to the colon then a right paramedian exploratory laparotomy must be performed, and the condition of the cæcum definitely ascertained. If distended I would, without any further exploration, advocate immediate blind cæcostomy, either through the original wound, if the cæcum will come readily up into it, or, as in most cases, after rapidly closing up the laparotomy wound, I would perform a blind gridiron cæcostomy. If the cæcum is found collapsed then the hernial orifices are rapidly examined from within, a collapsed coil of ileum is picked up from the right-hand side of the bottom of the pelvis, and is traced upwards to the site of the obstruction. It may be inquired, since I advocate blind cæcostomy as the method of choice for these late cases of obstruction of the colon, why do I not advocate blind enterostomy for obstruction in the small intestine. The difference is one of the relative frequency of the presence of strangulation. As I have shown, in the case of the large intestine after relief of the obstruction by cæcostomy, the risk of an unrelieved strangulation remaining undiscovered is at most 1·5 per cent. An analysis of Souttar's statistics shows that in the case of the small intestine, even after relief of the obstruction by an enterostomy, the risk of unrelieved strangulation remaining would be at least 42·6 per cent.

ENDOCARDITIS LENTA.*

BY GLADYS M. WAUCHOPE M.D.,
M.R.C.P. LOND.,
ASSISTANT PHYSICIAN TO THE NEW SUSSEX HOSPITAL FOR WOMEN AND CHILDREN.

THE name "endocarditis lenta" has never really become popular, though it well describes the more chronic forms of infective endocarditis. It was first used by Schottmüller in 1910 and applied to five cases of subacute infective endocarditis due to the *Streptococcus viridans* seu *mitior* (named from the green colour of the culture on blood-agar and its feeble hæmolytic powers), an organism which he had isolated in 1903. Later writers used the term to describe cases of subacute or chronic endocarditis due to any organism except that of rheumatism, and it is so used in the present paper.

Osler, in the Goulstonian lectures for 1885, drew attention to the more chronic forms of infective endocarditis, while Jaccoud recognised the condition at about the same time (1883), and later French writers refer to "le type Jaccoud-Osler" (Flessinger et Janet 1920). In 1908 Osler and Horder described very fully the clinical aspects, but the disease was somewhat rare until the war of 1914–18 when many cases were seen in soldiers, especially those who served on the Western front (Curschmann, 1922, Wauchope, 1925).

The present paper is based on 200 cases taken from the London Hospital records. Of these 131 were verified by autopsy; in the remainder a time basis has been employed to divide them from cases of acute infective endocarditis, no case being included in which definite symptoms of the illness were present for less than three months.

Ætiology.

The ætiology is obscure, but various predisposing factors are recognised.

TABLE I.—*Congenital Malformations of the Heart.*

Complete transposition of the heart and other viscera ..	1
Patent septum membranaceum..	1
Four cusps to pulmonary valve (infective endocarditis of mitral valve only)	1
Bicuspid aortic valve (one case associated with coarctation of the aorta)	5

1. *Previous Heart Disease.*—(*a*) Congenital lesions. It is well known that infective endocarditis often supervenes on gross congenital malformations; recently attention has been drawn to the influence of the bicuspid aortic valve in predisposing to endocarditis lenta (Lewis, 1923, Horder, 1926, Wauchope,

---

* A paper read before the Brighton and Sussex Medico-Chirurgical Society.

1928). The congenital lesions found in the London Hospital cases are shown in Table I.

(*b*) Acquired valvular disease. Syphilitic aortic endocarditis was present in only one of these cases, and is not considered a predisposing factor. Rheumatism is, however, of great importance, and the earlier writers, especially, e.g., Osler (1908), Horder (1908), and Schottmüller (1910), lay stress on the observation that more than half the cases had previous rheumatic cardiac lesions. Blümer in 1923 collected 330 cases from the literature and found a history of rheumatism in 140, of chorea in 10, and of tonsillitis in 18, the three together making over 50 per cent. In ex-Service men the proportion with previous rheumatism was less. Cotton, for instance, found a history of rheumatism in 29 per cent. of warpensioners. Morawitz (Würzburg) found it in 3 out of 17 ex-soldiers and Starling found rheumatic scarring in 1 only out of 13 autopsies. Histories are notoriously unreliable and everyone has seen cases of young people who had definite signs of mitral stenosis and yet denied having had any illness compatible with a diagnosis of acute rheumatism. On the other hand, post-mortem evidence is not conclusive because the extreme fibrosis and destruction of valves found in long-standing cases of endocarditis lenta may obscure the evidence of a previous rheumatic lesion. It is probably for this reason that most observers rely on the history, and although a negative history is worthless an analysis of the London Hospital patients who stated that they had had rheumatism, set out in Table II., may be of interest.

TABLE II.—*History of Rheumatic Fever or Chorea.*

—	Cases of endocarditis lenta.	Cases with history of rheumatism.	Percentage with history of rheumatism.
Civilian males ..	93	49	52·6
Ex-soldiers ..	40	9	22·5
Females	67	38	56·7
Total	200	96	48·0

In 17 males (none of them soldiers) and 11 females the heart was known to have been affected by a previous attack of rheumatism, while 8 males and 3 females said they had had "heart trouble" but no rheumatism. This gives percentages of 18·8 in all males and 20·9 in females who were known to have had a cardiac lesion before the onset of endocarditis lenta.

2. *Factors Connected with Army Service.*—Since previous heart disease was not an important predisposing factor in soldiers other causes have been suggested; wounds and infections (Cotton, 1920), lowered resistance due to fatigue (Coombs, 1923) or the strain of carrying a heavy pack (Murray and Lougheed, 1921). All observers agree that the disease occurred in strong healthy men of about 35 years of age who had withstood long service, generally in France.

Of the 40 London Hospital patients who had been in the army 30 at least served in France and the histories of the majority point to long and strenuous service; 15 had been wounded and 11 gave a history of some febrile condition such as trench fever, influenza, septic poisoning.

3. In women *childbirth* may be the starting-point of the disease. Four of the patients in this series were confined 18, 13, 10, and 7 months before death; in one the labour was said to have been difficult. A fifth miscarried four months before death, but this was probably the result of the illness, although the symptoms dated from the miscarriage.

4. In two patients *wholesale extraction of septic teeth* seemed to give rise to the infection, and I have seen another case since in which this sequence appeared clear.

The Infecting Organism.

This, in the majority of cases, is a short-chained non-hæmolytic streptococcus, the *Streptococcus viridans.* Libman (1923) states that 95 per cent. of cases are due to this organism, the remainder being nearly all due to Pfeiffer's bacillus. Blümer (1923) gives the following results from an analysis of the literature of 304 cases of infective endocarditis lasting for more than three months:—

Streptococcus	248*	Staphylococcus	8
Pneumococcus	16	Gonococcus	1
Bacillus influenzæ ..	16	Other organisms ..	15†

* Of which 169 were *S. viridans.* † Including 7 unclassified.

In 110 of the London Hospital cases an organism was identified before or after death, of which 73·6 per cent. certainly, 84·5 per cent. probably, were streptococcal (Table III.).

TABLE III.

Organisms identified.	Cases.	Organisms identified.	Cases.
Streptococcus	81	Unspecified Gram-positive cocci in culture ..	3
Staphylococcus	6	Gram-positive cocci in films	9
Pneumococcus	4		
Gonococcus	2		
Micrococcus catarrhalis ..	2		
Bacillus influenzæ ..	3	Total	110

Prof. H. M. Turnbull has pointed out to me that the above table cannot be accepted as giving the organisms responsible for the endocarditis lenta in individual cases. The organisms cultivated before or after death are not necessarily the cause of the endocarditis lenta. Microscopic sections are essential in determining the organism responsible for this peculiar kind of endocarditis. When only one kind of organism has been found within the valves in microscopic sections it has been found in almost all cases to be an extensively degenerated, Gram-positive streptococcus, presumably *S. viridans,* grouped in large masses; but in a few cases Pfeiffer's *B. influenzæ* or the gonococcus has alone been found. The cases in which the gonococcus or *B. influenzæ* was alone found were clinically in the length of their course less sharply differentiated from examples of acute infective endocarditis than were the other examples of endocarditis lenta. When organisms such as pneumococci and staphylococci had been cultivated, the sections of the valves showed the characteristic large masses of degenerated streptococci in addition to the pneumococci or staphylococci. That these latter organisms were not the cause of the endocarditis but a secondary infection was shown by their relative sparsity, by their limitation to the surface of the vegetations, or their presence within new vessels formed during the chronic inflammation of the valve, and by their being surrounded by a purulent reaction, which is not found in pure endocarditis lenta. Similar findings and conclusions were arrived at independently and have been published by Wright in an important paper (1925).

Secondary pneumococcal infection is frequently the result of a terminal pneumonia. This was true of two of the four cases in the above table, the pneumonia in one case being complicated by pneumococcal bacteriæmia and meningitis. In other respects the pneumococcal cases were similar to the cases of streptococcal endocarditis lenta.

The six staphylococcal cases also differed in no way in their clinical course from the cases of streptococcal infection, and this confirms the conclusions drawn from post-mortem appearances that these organisms are a terminal infection supervening on a streptococcal endocarditis. All the patients were men. One case was observed for eight months, another for over five, and another was a typical chronic case in a soldier lasting for a year. Staphylococci in pure culture were grown from the blood during life in all six cases; in one the culture had been sterile four days previously.

The two cases due to the gonococcus followed the usual course of gonococcal endocarditis and were both clinically and pathologically more subacute than chronic. Both occurred in women.

The first case, an unmarried girl of 20, was admitted to hospital early in November, 1922, with a tubo-ovarian abscess and pyosalpinx (found at laparotomy) and was observed till her death three and a half months later. The temperature never settled after the operation though the wound healed satisfactorily; a mitral murmur appeared in December and the blood culture grew gonococci in January, a month before death. The diagnosis was verified at autopsy, the mitral valve only being affected.

In the second case, a married women of 40, the illness ran a more chronic course and lasted for five months. There was no history of the original infection, but her husband had had gonorrhœa three years before, and though treated suffered from gleet. The illness began with symptoms of heart failure, and for the last six weeks of life the temperature was irregular and remittent, rising to a maximum of 103° F. Gonococci were cultured from the blood a week before death. The aortic, mitral, and tricuspid valves were covered with typical vegetations and the other post-mortem findings were those of endocarditis lenta.

Two of the three cases due to *B. influenzæ* were of six months' duration and in both the blood culture was sterile during life, but the organism was isolated after death. One of these patients died from cerebral embolism. The course of the third influenzal case was less chronic, three months in duration, with a remittent temperature reaching 103° F. The organism was twice cultured from the blood during life. Both the *M. catarrhalis* cases were febrile, one associated with rigors; in both emboli occurred and in both the blood culture was positive.

The more chronic the course of the illness the more often is the blood culture sterile. Libman (1925) distinguishes a bacteria-free stage in which the blood cultures are sterile and the vegetations at autopsy show few or no bacteria. Wright (1925) has shown that growth in blood cultures occurs even if the organisms are present in very small numbers, though in cases of streptococcal endocarditis it is often delayed. He pointed out that bacteriæmia is secondary and is due to the escape of organisms from the valves and that in the non-bacteriæmic cases the organisms are either dead or are prevented from reaching the blood stream by thrombus material. This non-bacteriæmic stage corresponds to the chronic type of the disease found in soldiers (Wauchope 1925). Among the 26 cases in soldiers in this series, where a culture was made, in four only (15·4 per cent.) was it positive, while in the 114 civilian cases examined it was positive in 68·4 per cent. In six only of the sterile civilian cases an organism was identified from the vegetations on the valves, but in seven of the soldiers.

Incidence.

The *sex-incidence* was altered by the war cases. Earlier writers note that the sexes were almost equally affected—e.g., Osler and Horder in 1908. Schottmüller in 1910 records 3 males to 2 females. Blümer in 1923 in the literature found 107 males to 131 females, a proportion of 3 to 2. The war brought a preponderance of males, especially in the chronic cases. In this series there were 133 males and 67 females, about 2 to 1, while in cases of over six months' duration the proportion was 3·4 to 1.

TABLE IV.—*Age-incidence of the London Hospital Patients.*

Age ..	10 to 19.	20 to 29.	30 to 39.	40 to 49.	Over 50.
Males	15	54	31	23	9
Females ..	10	32	14	10	2
Total	25	86	45	33	11
Percentage ..	12·5	43	22·5	16·5	5·5
Soldiers ..	—	16	15	8	1

Age-incidence.—The greatest number of cases occur in the decade between 20 and 30, the next in that between 30 and 40 (cf. Horder, 1908, Blümer, 1923). Of the London Hospital cases 65·8 per cent. occurred in patients between 20 and 40 (see Table IV.). In Osler's cases the men were older than the women, and this was the case at the London Hospital, where of the men 47 per cent. were over 30 while of the women 38·8 per cent. were over 30. The disease seems to be more chronic in older patients, and it is significant that in soldiers in whom the chronic type was seen so often, 60 per cent. were over 30. Becher (1921), Cotton (1920), and Curschmann (1920) record similar experience.

Initial Symptoms.

The onset is usually insidious and gradual, but in a few cases the patient is apparently well until, with dramatic suddenness, an embolus occurs. This happened to 11 of the patients in this series. Examples: A man of 41 had a left hemiplegia while serving with the army in France, another while playing billiards. A third, aged 25, was found semi-conscious on Epsom Downs on June 2nd, 1920; the more usual causes of this condition on Derby Day were excluded and a diagnosis of infective endocarditis with right hemiplegia was established. The patient had a second cerebral embolus on Nov. 14th and died the next day. In a fourth case the first symptom was sudden blindness of the left eye due to an embolus of the central artery of the retina. Three patients died within a few hours of the first embolus; the notes of one case, a woman of 28, record "stooping down to unlace boots, fell down, brought in dead."

A study of the histories shows that there are four principal groups of symptoms by which the disease first shows itself—viz.: (1) symptoms referred to the heart; (2) symptoms of rheumatism; (3) symptoms of a febrile illness; and (4) symptoms of indefinite ill-health.

(1) *Cardiac.*—The first symptoms are those of chronic heart failure; the infective attack which brought about the damage to the heart has passed unnoticed. The patient complains of increasing breathlessness, cough, swelling of the feet; "pains over the heart," and occasionally palpitations are mentioned.

(2) *Rheumatic.*—The patient, who may or may not have had acute rheumatism before, has a definite feverish illness accompanied by painful joints. This does not subside when salicylates are given in full doses and eventually the diagnosis is revised. Some cases are less definite and pain in the limbs or in one particular joint is an incident in a general feeling of discomfort.

(3) *Influenzal or Febrile.*—The history is given that the patient had an attack of "influenza" some months or weeks previously and has not been well since; sometimes it is a "chill," or a "bad cold" from which the patient only partially recovers. In other cases a sudden attack of fever or shivering ushers in the final phase of the illness and causes the patient to seek treatment.

(4) *Indefinite Ill-health.*—The patient suffers from general malaise, weakness, and wasting, which continue and increase for several months. Feeling "queer," "run down," "sleepy," "languid," "out of sorts," are expressions used. One patient complained of feeling irritable. Headache, loss of energy, and insomnia are common; loss of weight is often mentioned, but there are no localised symptoms.

(5) The next most common group of cases is that in which *abdominal pain, vomiting,* and *diarrhœa* announce the presence of the illness. Sudden pain in the back recorded in four cases may be due to embolism.

The relative frequency with which the various initial symptoms were found is shown in Table V.

When the patient comes under observation the clinical picture is usually quite definite. He is pale and breathless on exertion and there may be œdema of the feet. The temperature is irregular, the heart considerably enlarged, particularly to the left, and there are loud murmurs generally at both mitral and aortic areas. One or more of [illegible] characteristic signs [illegible]: pa[illegible] [illegible]bing of the fingers, purpura, Osler nodes and other signs of embolism; last, and most important, is albuminuria, sometimes with hæmaturia and the presence of casts.

Clinical and Pathological Features.

Perhaps it will be useful to consider in detail some of the more important clinical aspects of the disease, correlating them where possible with the pathological foundations.

1. The *general condition* of the patient is generally better than would be expected in so serious and long-continued an illness, and the symptoms are less evident than the physical signs. Euphoria is characteristic and the patients have none of the restlessness and anxiety associated with other cardiac conditions, but in spite of breathlessness, fever, or partial paralysis continue placid and contented with a firm belief in their ultimate recovery.

A man of 39 came to the hospital because his feet had swelled and he could not get his boots on. The disease was well advanced and he was told he was very ill, but after six weeks, as the swelling of the feet subsided with rest in bed, he went at his own request to a convalescent home and then returned to his work as a fish porter in Billingsgate Market—heavy work for a man with a failing heart, grossly enlarged spleen, nephritis, and fever. He continued for three months, getting up at 5 A.M. and going to bed in the afternoon as soon as his work was over. Even when he was obliged to return to hospital, where he spent the last three months of his life, he had a feeling of well-being and remained hopeful.

2. The *temperature* is irregular and is rarely of the remittent "septic" type associated with acute infective endocarditis. In the more chronic cases there are often long periods of apyrexia; one man was observed for six weeks with 99° F. as the maximum, and the only reaction after an injection of antistreptococcal serum was a rise to 100° F. Such cases are practically afebrile, but as most of the patients in this series were under observation in the later stages of their illness when fever is more common there was no instance in which the disease was observed for 14 days or more without an occasional rise to at least 99° or 100° F. In many of the less chronic cases the temperature occasionally rose to 102° or 103° F.; in others it was remittent with a maximum of 103° F. for a few days or a week and then fell irregularly; a rise to 104° F. was rather unusual. The irregularity of the fever is its main characteristic.

3. The *heart* is nearly always regular in its action and the rate of the beat is relatively slow in spite of two causes for acceleration—viz., heart failure and a streptococcal septicæmia. The rate in the chronic cases was about 70–90 per minute for weeks together, and often failed to rise in occasional attacks of pyrexia. In the subacute cases, when the temperature rose to 102° or 103° F., the pulse-rate was rarely over 120. Sometimes, but by no means always, it became rapid shortly before death. The heart is considerably enlarged to the left; loud murmurs are usually heard both at the mitral and aortic areas; signs of heart failure—œdema, ascites, and breathlessness—develop. Libman (1923) noted sternal tenderness in some of his cases, particularly late in the disease.

The *post-mortem appearances* of the heart correspond with the clinical findings.

(*a*) Hypertrophy of the cardiac muscle is constant, and the distribution in any case is compensatory to the particular interference with valvular function. Microscopic myocardial lesions are not uncommon and are embolic in origin; larger infarcts and areas of fibrosis are rare (Coombs 1921). In this series infarction or fibrosis occurred in 31 cases. (Table VII.)

(*b*) Pericarditis almost never occurs, but the remains of an extensive pericarditis due to rheumatism is sometimes found, whilst milk spots and fibrous tags, probably due to rheumatism, are extremely common.

(*c*) The endocarditis is a pure endocarditis, in contrast to rheumatic carditis where pericardium, myocardium, and endocardium are usually all affected. The mitral and aortic valves are generally both involved—in 63 per cent. in a series of 110 cases—though one valve alone or three or even all four may be attacked; the aortic valve is more often affected in endocarditis lenta than in rheumatism (Wauchope, 1928). It is noteworthy that in the seven cases due to the gonococcus, *B. influenzæ*, and *M. catarrhalis* the distribution of the endocarditis was rather different from that found in the streptococcal cases; the mitral valve was affected in each case; alone in five; the mitral severely and the aortic slightly in one (*B. influenzæ*); the mitral, aortic, and tricuspid in one (gonococcal). The affected valves are covered with polypoid vegetations, fibrinous and tough at the base, and in the more chronic cases impregnated with small particles of calcium. There is usually much destruction and considerable fibrosis of the valves. The mural endocardium adjacent to the affected valve is often involved. Mural endocarditis of the left auricle is frequent, and it is common to find endocarditis of the aortic cusps spreading on to the endocardium of the left ventricle.

4. *Kidneys.*—Albuminuria is the most constant clinical feature to be associated with the cardiac signs and pyrexia. It occurred in over 80 per cent. of these cases (see Table VI). In the majority it was due to nephritis which was present in 64 per cent. of the cases which came to autopsy; sometimes albuminuria was associated with back pressure kidney or simple parenchymatous degeneration. Hæmaturia, visible to the naked eye or microscopic, was noted in 43 per cent. of the cases; it may be due to nephritis when it is often associated with casts; to infarction, when it is temporary, or to purpura when it is profuse.

TABLE VI.—*Clinical Observations (excluding Cardiac Conditions).*

	Cases and Per cent.		Cases and Per cent.
Albuminuria ..	152 (81·7)*	Clubbing of the fingers	71 (35·5)
Hæmaturia ..	86 (46·2)*	Purpura	59 (29·5)
Palpable spleen ..	109 (57)†	Osler nodes	16 (8·0)
Gross embolism ..	99 (49·5)		

* 14 cases not tested. † 10 cases notes defective.

The nephritis is of two types: (1) A hæmorrhagic nephritis characterised by the so-called "focal embolic glomerular necrosis" of Löhlein (1910). It was described by Baehr (1912 and 1921), who studied the microscopic appearances of the kidneys and found this type of nephritis in subacute streptococcal endocarditis, but not in cases of endocarditis due to other organisms. (2) A diffuse hæmorrhagic nephritis without "focal necrosis" is present in other cases. Death from uræmia is a not uncommon termination.

5. *Spleen.*—Enlargement of the spleen is frequent and is an important diagnostic point. In the more chronic cases it is often very big, reaching as far down as the umbilicus. It was felt on clinical examination in 57 per cent. of these cases (Table VI.) and was certainly enlarged in a greater proportion. The percentage of cases in which at autopsy it was found to be 9 oz. or over in weight was 86 (normal 4–6 oz.). In 50·4 per cent. it weighed over 1 lb., in seven cases over 2 lb., and in one case 3 lb. 11 oz. The possibility of feeling it clinically depends on several things besides the degree of enlargement: (1) Careful and frequent examination; (2) the thickness of the patient's abdominal wall; (3) the condition of the

spleen itself. A hard, firm spleen is easily felt while a soft œdematous organ of much greater size cannot be defined—e.g., two spleens found to be 9 oz. on weight had been palpable during life, while in another case where the weight was 1 lb. 7½ oz. there was no indication of splenic enlargement before death.

In Prof. Turnbull's experience the spleen at necropsy is characteristically a chronically inflamed spleen. It is greatly enlarged and firm, and shows upon the cut surface trabeculæ and enlarged Malpighian bodies. Microscopically the pulp shows an infiltration of a chronic type, the majority of the infiltrating cells being plasma cells and large mononuclear cells with deeply basophil cytoplasm. Occasionally, however, in the typically chronic cases a spleen showing little or no enlargement is found at necropsy. Death is then due to heart failure and the spleen is of the "back pressure" variety. It appears, therefore, that the inflammation and consequent enlargement of the spleen may diminish in intermissions of the bacteriæmia; such intermissions can be recognised on the temperature chart during life. These variations in the bacteriæmia and consequent size of the spleen can explain failure to palpate the organ or discrepancies between clinical and post-mortem findings.

In a number of cases pain in the splenic area was followed by a rapid enlargement of the organ and infarcts were found after death. If these events are correlated the enlargement must be due to œdema or inflammation caused by the embolism and not to the infarct itself, which is not larger than the healthy tissue it replaces. Post-mortem infarcts are found more often in the spleen than in any other organ (see Table VII.).

6. *Embolic phenomena* are an important part of the disease. Instances have been given of cases in which they provide the first symptom; more often they cause striking incidents in the course of the illness. Attacks of renal pain followed by hæmaturia; pain in the left hypochondrium followed by rapid enlargement of the spleen; cough with expectoration of blood-stained sputum—a definite hæmoptysis occurred in four patients—attacks of gastro-enteritis with abdominal pain, associated with embolism or thrombosis of the mesenteric or cœliac arteries. In all these instances and in the cases of hemiplegia the clinical signs and the post-mortem findings are correlated—for instance, in an unusual case of a woman aged 26 swelling of the right arm appeared six days before death, followed by great and increasing œdema, and at the autopsy thrombosis of the right internal jugular vein and innominate vein was found. In the myocardium, however, although infarction and fibrosis are fairly common at autopsy, it is rare to find any clinical record of the actual attack. Table VII. shows the localisation of the emboli in the London Hospital cases.

Embolic aneurysms are not uncommon, and one remarkable case must be recorded.

A girl of 13 was admitted to hospital on April 10th with one week's history of severe abdominal pain. A nodule was present just above and to the right of the umbilicus. This disappeared, but in May returned and increased in size. The patient's symptoms, however, subsided, and she was discharged in June. Six weeks later she was readmitted, complaining of "a lump in the stomach." The nodule was now 2 in. in diameter, was movable, hard and dull on percussion. It was not fluctuating and non-pulsatile. The provisional diagnosis lay between a retroperitoneal sarcoma and tuberculous adenitis. Signs of endocarditis were present, but the child had had two attacks of rheumatic fever and the blood culture was sterile. Laparotomy was performed under stovain. An aneurysm of the mesenteric artery burst as soon as the peritoneum was opened and the patient died an hour later. Post mortem an infective aneurysm (10 × 5 × 6 cm.) was found replacing the superior mesenteric artery 4 cm. from its origin. Infective endocarditis of mitral and aortic valves was present with the usual associated conditions of the kidneys, spleen, &c.

Post-mortem embolic aneurysms were found in the distribution shown in Table VII.

Embolic lesions of great diagnostic value are Osler nodes. These are red raised painful spots which occur on the fingers and toes and last for a few days. They were noted in only 8 per cent. of the London Hospital cases (Table VI.).

7. *Clubbing of the fingers* is an interesting phenomenon which seems in these cases to depend on the toxæmia more than on a mechanical defect in the circulation. It has been observed to diminish (Libman, 1925), but in general depends on the duration of the disease. It was noted in 35·5 per cent. of the London Hospital cases (Table VI.).

8. *Blood Conditions.*—The anæmia is a slowly progressive secondary anæmia. In one chronic case the red cells were 3,140,000 and the hæmoglobin 55 per cent. in May, while in December the red cells were 2,100,000 and the hæmoglobin 35 per cent. In another the count was 4,300,000 in April and 3,200,000 in June. The lowest count in the series was 1,200,000 with 30 per cent. hæmoglobin, while in 86·4 per cent. of those examined the red cell count was under five millions. In three cases (5 per cent. of those examined) there were over six million red cells, in one the count was made about a month before death, the other two were discharged with symptoms improved, but physical signs unchanged. The anæmia sometimes leads to the "earthy" or café au lait" complexion mentioned in the literature. Amenorrhœa unconnected with pregnancy was noted in 16 (23·9 per cent.) of the women. Leucocytosis is not characteristic; it was found in only 25·4 per cent. of the counts made and was often slight—e.g., 11,000 or 12,000 white cells with a relative polymorphonuclear increase up to about 85 per cent. In one case there were 35,999 white cells with only 35 per cent. of polymorphonuclear cells and 37 per cent. myeloblasts, an unusual complication. Leukopenia is more common than leucocytosis, and occurred in 58·7 per cent. of the cases examined, the lowest count of 1920 white cells, of which 44·5 per cent. were polymorphonuclear cells, was associated with a very low red cell count. Purpura was noted in 20·5 per cent. of these cases, and is probably a result of the bacteriæmia, though it may be due to anæmia; it usually occurs as crops of petechiæ; allied manifestations are *epistaxis, retinal* and *subconjunctival hæmorrhage, melæna, hæmaturia,* and *bleeding of the gums.* In one long-continued case all these were noted at different times except bleeding of the gums. A cutaneous eruption of "free hæmorrhagic bullæ over the face and arms" was described by Coombs (1921) and is probably analogous to the purpura and other hæmorrhagic occurrences. It was observed in three of the London Hospital patients and was in each case diagnosed as a halogen rash. Dermatologists recognise that patients suffering from severe cardiac and renal disease are particularly liable to this type of iodide eruption (Sequeira, 1927), and in each of the three cases the amount of iodide given was small and the patient was seriously ill.

In one case the eruption appeared after grs. 90 of potassium iodide taken in gr. 10 doses three times a day. It was symmetrical, beginning as purpuric papules, and developed into hæmorrhagic vesicles about the size of a sixpence surrounded by purpuric patches. It began to fade on the fourth day (the iodide had been suspended) and the patient died eight days after its appearance.

For another patient, a woman, potassium iodide, grs. 5 three times a day, was ordered on May 18th for four days; the rash appeared on May 21st and was still present on May 29th; the patient died on June 11th.

The third patient, like the first, was a man. He was ordered grs. 3 of potassium iodide three times a day for three weeks as an out-patient. The iodide was then apparently suspended, and when the patient was admitted a week later the eruption was present. He died four days after admission.

Diagnosis.

Diagnosis is not usually difficult, but sometimes one aspect of the case predominates and may mislead for a time.

1. *Acute rheumatism* is a frequent early diagnosis, and those cases which first come under observation with pains in the joints, fever, and a cardiac lesion are indistinguishable from rheumatism until the therapeutic test of administering salicylates is applied, unless, of course, an enlarged spleen or other complication raises a doubt. Albuminuria and purpura may be associated with rheumatic endocarditis; clubbing of the fingers may be present if the heart was severely damaged by a first attack in childhood; embolism occasionally occurs but Osler nodes are said to be diagnostic of endocarditis lenta and to occur in no other disease.

2. Some cases resemble *typhoid fever*—e.g., that of a woman of 25 who had an illness diagnosed as influenza four months before admission to the hospital and had been "languid and out of sorts" since. She complained of headache, pains in the legs, sweating, and diarrhœa. The tongue was heavily furred and the spleen was palpable, the temperature was irregular, rising to 103° F., and leukopenia completed the picture. There was a mitral systolic murmur and clubbing of the fingers which could be accounted for by an attack of rheumatism at the age of 16. The Widal reaction was, however, negative, and the blood culture grew non-hæmolytic streptococci on two occasions. Autopsy revealed typical lesions of the aortic and mitral valves, subacute lipoid nephritis, and splenic and renal infarcts.

3. Gastro-intestinal symptoms dependent on large emboli have led to a diagnosis of *acute gastro-enteritis* and even simulated *intestinal obstruction.*

4. Cerebral embolism and hæmorrhage are puzzling if the patient is unconscious when first seen.

5. Sometimes the evidence of renal disease and uræmia lead to a diagnosis of *nephritis*, the underlying cause being overlooked.

6. An *aneurysm* may be the presenting sign, as in the case quoted of an abdominal tumour and in the case of a man of 24 who was admitted with a large swelling in the thigh which proved to be a false aneurysm connected with the arteria profunda femoris.

Prognosis and Treatment.

Prognosis is regarded in this country as practically hopeless. Only 33 (16·5 per cent.) of these patients did not die while under observation; four were definitely worse on discharge and none showed any real signs of recovery, though in eight the symptoms were alleviated. Libman (1925), however, records at least ten cases of recovery, one patient being free from all symptoms as long as 11 years after definite signs of the disease, including Osler nodes and a positive blood culture had been observed.

Treatment has so far proved futile. Vaccines, serums, intravenous medication with colloidal metals, colloidal iodine, mercurochrome, arsenic and its derivatives, especially sodium cacodylate, have all been tried. The oral administration of sodium sulphocarbolate was at one time popular. Blood transfusion may improve the general condition, but has no specific action. No treatment appears to have any permanent beneficial effect; the best result obtained was a temporary lowering of the temperature. At present our power to help is limited to general treatment, open air, and attention to the patient's comfort and happiness, and I do not think that we should be deterred by fear of embolism from allowing the patient to lead as active and normal a life as he feels inclined to do. Emboli occur even in bed and, on the other hand, a sudden death or the curtailment of a few weeks of life is in many cases to be preferred to the death from progressive heart failure, toxæmia, or uræmia, which will inevitably occur.

I wish to thank the physicians of the London Hospital for permission to use the notes of their cases; Prof. Turnbull for permission to use the records of the Bernhard Baron Institute of Pathology; and Dr. G. T. Western, for permission to use the results of the bacteriological investigations. I am greatly indebted to Prof. Turnbull for the observations under his name which have been included in the text.

SPLENIC ANÆMIA.

THE NECESSITY FOR EARLY OPERATION.

BY A. CECIL ALPORT, M.D. EDIN., M.R.C.P. LOND.,
ASSISTANT IN THE MEDICAL UNIT AT ST. MARY'S HOSPITAL.

SPLENIC anæmia, as a clinical entity, was first described by Gretzel in 1866, and later in the same year the name "splenic anæmia" was given to the disease by Griessinger. The condition is characterised by an enlarged spleen, secondary anæmia, leucopenia and, as a rule, a relative lymphocytosis.

In 1883 Banti, of Florence, first described the phase of the disease which goes by his name. Banti's disease is merely a late stage of splenic anæmia complicated by cirrhosis of the liver. Banti's hypothesis is that there is a primary splenomegaly due to an infective agent, and that the splenic enlargement itself produces another toxin which, acting on the liver and on the splenic veins, produces the changes found in Banti's disease, the anæmia being the result partly of toxæmia and partly of hæmorrhage.

Naunyn and others consider that splenic anæmia is primarily a cirrhosis of the liver, and that the enlargement of the spleen is always secondary to early changes in the liver. Osler and McCrae[1] describe splenic anæmia as "a disease of the spleen of unknown origin characterised by progressive enlargement, anæmia, a tendency to hæmorrhage, and in some cases a secondary cirrhosis of the liver with jaundice and ascites. That the spleen itself is the real seat of the disease is shown by the fact that complete recovery may follow its removal." There can be no doubt that Osler's reasoning is sound, and that the disease is primarily splenic in origin. It is probably the result of a toxin from some infective process located in the spleen. Thursfield[2] states that it is certain there are cases of splenic anæmia where the stage of cirrhosis is never reached, and that the termination of the disease may be either fatal anæmia or an equally fatal cirrhosis.

The question of splenectomy in the treatment of splenic anæmia is thus of the greatest importance. Pearce, Krumbhaar, and Frazier[3] state that as a general fundamental principle the best results from splenectomy are obtained in those diseases in which there is evidence of increased blood destruction. Such cases would include hæmolytic jaundice and splenic anæmia, and also Gaucher's disease, von Jaksch's disease, and pernicious anæmia, in which splenectomy has been tried.

To obtain satisfactory results in splenic anæmia, early operation is absolutely essential. If there is definite impairment of hepatic efficiency, splenectomy is contra-indicated because of its dangers. Even if the spleen be successfully removed in splenic anæmia with cirrhosis of the liver (Banti's disease), the secondary changes in the liver are not influenced and the hepatic degeneration continues, although the progress of the disease is retarded and the life of the patient prolonged. This accounts for the necessity for operation as early as possible. The greatest care should be taken before operation to eliminate the atypical forms of leukæmia. Splenic anæmia was described by H. C. Wood in 1871 as the splenic form of pseudo-leukæmia. Splenectomy in leukæmia almost invariably results in the death of the patient. A. van Verts, in 1898, collected 25 cases of splenectomy in leukæmia, and C. Fevrier, in 1901, two cases. Of these only three survived, and Banti himself considered that one of the latter, Franzolini's case, was really a case of Banti's disease and not leukæmia at all.

Two Contrasting Cases.

The results of splenectomy in the two cases described below have a definite bearing upon the question of early operation in cases of Banti's disease, and as such are, I think, worth recording. They are the more interesting in that they are familial. The patients were sisters; both developed splenic anæmia followed by liver changes, and both had splenectomy performed. The one operated upon in the early stages of liver involvement recovered; the other, suffering from more advanced hepatic changes, died.

CASE 1, *aged 35 years, married*, was admitted under Prof. F. Langmead to the medical unit wards of St. Mary's Hospital on April 13th, 1926. She had had ulcers in the mouth and pallor since girlhood, and a lump in the abdomen since 1918. In January, 1926, she had had a labour induced owing to the impossibility of full-time delivery; the baby was dead. Afterwards "she was delirious for a week," and was told at the time that "her kidneys were bad." Her father had Bright's disease, and two brothers had died of tuberculosis.

On admission her general condition was fairly good, but her colour sallow. A blood examination gave the following result: red cells, 4,288,000 per c.mm.; white cells, 2500 per c.mm.; hæmoglobin, 58 per cent.; colour-index, 0·68; polymorphonuclear leucocytes, 78 per cent.; small lymphocytes, 12 per cent.; large lymphocytes, 0 per cent.; eosinophils, 1 per cent.; nucleated red cells and some immature leucocytes present; Wassermann reaction negative. There was no enlargement of glands, but the spleen was much enlarged, the lower pole reaching well below the umbilicus in the right iliac fossa. The liver dullness was diminished and the hepatic efficiency impaired. Banti's disease was diagnosed.

On June 3rd, 1926, splenectomy was performed by Prof. C. A. Pannett. The spleen showed peri-splenitis and was very adherent. The splenic and inferior mesenteric veins were enormously dilated, and there was considerable loss of blood during the operation. The patient afterwards was much shocked and remained semi-comatose until June 5th, when she sank into deep coma (cholæmia) and died.

The spleen was firm, dark red, and about seven times the normal size, weighing 1700 g. The liver was small, thin, dark in colour, and about two-thirds of the normal size. The surface was roughened and thickened in places, and the portal and splenic veins were thrombosed.

It should be noted that this patient was sent into hospital eight years after a "lump" had been discovered in her abdomen, and the only means of prolonging her life was successful splenectomy. Before her operation we had had in the wards a case of Banti's disease with cirrhosis of the liver and ascites, which had been operated upon with excellent results. In these advanced cases, however, the operative risk is always greatly increased, and it is a short-sighted policy to postpone the consideration of splenectomy for years, until the only alternatives are a painful lingering death on the one hand, or the risk of a fatal result to the operation on the other.

CASE 2, aged 42 years, married, had had slight anæmia for five years. In December, 1926, she began to feel ill, her menstrual periods occurred every fortnight, and lasted for five to seven days, and she became more anæmic. She was kept in bed for three months by the doctor, who told her she had an enlarged spleen. In April, 1927, she had a severe uterine hæmorrhage, and was in bed for five weeks as a result. In October, 1927, she came to London to see a specialist, who advised admission to hospital, but she refused. On April 23rd, 1928, she was sent by her doctor to consult me. She had pain and swelling on the left side of the abdomen, did not feel fit, and was unable to carry on her work. The spleen was enlarged down to the umbilicus. The liver was not palpable; on percussion the lower level of the hepatic dullness was found two fingers' breadth above the costal margin. Blood examination gave the following result: red cells, 4,608,000; white cells, 3100; hæmoglobin, 70 per cent.: colour-index, 0·76; poikilocytosis and anisocytosis present; polymorphonuclear leucocytes, 76 per cent.; large lymphocytes, 5 per cent.; small lymphocytes, 12 per cent.; neutrophil myelocytes, 3 per cent.; transitionals, 4 per cent.; coagulation time of blood, two minutes. Routine examination of the urine revealed 0·64 per cent. of sugar, but no acetone or diacetic acid. After 50 g. of glucose had been taken the blood-sugar rose from its fasting level of 0·117 per cent. to 0·246 per cent. in one hour, 0·32 per cent. in an hour and a half, and to 0·255 per cent. in two hours. The Wassermann reaction was negative. X ray showed shadows in both antra of Highmore and on washing-out flakes of mucus were found.

I recommended immediate admission to hospital and splenectomy, but, although the patient herself was prepared to undergo the operation, her relatives refused to consider it on account of the fatal result in her sister's case. From time to time during the next five months I unsuccessfully urged operation. On Oct. 3rd, 1928, she agreed to come into St. Mary's Hospital for liver efficiency tests. A definite amount of urobilin was found in all the specimens of urine, suggesting some impairment of liver function. 40 g. of pure galactose, with a rotatory power of not less than 76, were given. The amount of sugar passed in the urine during the next three hours amounted to 2·61 g. The normal amount would be 1·5 to 3 g. in the first three hours. In definitely *disordered hepatic function the sugar passed in the first* three hours is 3 g. or more. In advanced cirrhosis of the liver it may be as much as 30 g.

Blood-sugar.	Fasting.	One hour.	Two hours.
(*a*) Normal case	0·085	0·11	0·09
(*b*) In cirrhosis	0·08	0·19	0·37
(*c*) In patient's case ..	0·07	0·134	0·134

As the *urinary sugar* was within the normal limits I recommended an exploratory laparotomy for the purpose of examining the condition of the spleen and, more particularly, of the liver. If the latter showed any definite degree of cirrhosis, splenectomy would not be attempted. The patient was prepared to agree to this, but again her relatives and friends persuaded her to refuse operation. She left the hospital after a week, and I was forced to desist from any further attempts to get the spleen removed. Before she left, however, I again explained the situation very plainly to her. If she underwent the operation successfully there was the prospect of good health for many years. On the other hand, like her sister, she might not survive the operation for more than a few days. The third alternative was no operation, with the prospect of gradual deterioration, the possibility of a sudden fatal hæmorrhage, and at the best a lease of life of not more than four years.

The choice was one not easily made, but ten days later she appeared at the hospital prepared for immediate operation. She had overcome the opposition of her family by pointing out that if, because of them, she did not undergo the operation, she would, when she was dying in two or three years' time, ask them why they had prevented her from seizing the opportunity of recovery whilst there was still time. Under the circumstances her action was a very brave one. On Oct. 18th, 1928, she was operated upon by Prof. Pannett, under a general anæsthetic, C_2E_3 and open ether.

Deep anæsthesia had to be induced by using chloroform for a few minutes, but chloroform is absolutely contra-indicated in cases with any degree of cirrhosis of the liver on account of its degenerative effect on the liver cells.

A left paramedian incision was made, the peritoneal cavity opened, and the abdominal contents examined. There was very little evident cirrhosis of the liver, although the organ was smaller than normal, and it was decided that it would be safe to proceed with splenectomy. The spleen was bound down by adhesions on the anterior surface of the lower pole, the pedicle, and the upper pole. The vessels in the adhesion were much enlarged and were ligatured and divided in the usual way, and the hæmorrhage on the whole was not very severe. On account of the density of the adhesions the operation took nearly an hour and a half, which is another strong argument in favour of early surgical interference in these cases. There was a considerable degree of shock, but on the whole the patient stood the operation fairly well. On her return to the ward her pulse-rate was 132, and she was given three pints of saline per rectum and an injection of morphia gr. ¼. The next day, Oct. 19th, she was very drowsy and difficult to rouse. She was given 500 c.cm. of intravenous saline, with 5 per cent. glucose, followed by 10 units of insulin. She suffered from very severe dyspnœa and a pulse-rate of 136; atropin gr. 1/150 was given hypodermically, and rectal salines with 5 per cent. glucose four-hourly during the night. There was slight improvement in the morning. On the 20th she experienced much discomfort from abdominal distension, but the flatulence was relieved by a turpentine enema. Her temperature was 101° F., and her pulse-rate 88. Next day she had severe præcordial pain, and on the 22nd was again very drowsy and of a bad colour, with a temperature of 102° and a pulse-rate of 88. Saline with glucose was given per rectum. Examination of the lungs showed only a few moist râles at the bases. On the 27th she complained of pain in the left groin and very severe headache. On the 28th she was very drowsy again during the day and fatigued at night. The stitches were removed on the 30th; the wound had healed perfectly. She still had great pain in the left groin, but no evidence of femoral thrombosis.

By Nov. 4th her general condition was slowly improving. Her temperature fell to normal for the first time, but she continued to have rises of temperature, up to 100·6° until the 24th, due, no doubt, to gradual absorption of toxic products from the thrombosed gastro-splenic vessels.

A blood count taken on Nov 29th showed red cells, 4,600,000 per c.mm.; white cells, 10,600 per c.mm.; hæmoglobin, 70 per cent.; colour-index, 0·76; polymorphonuclear leucocytes, 52 per cent.; large lymphocytes, 5 per cent.; small lymphocytes, 28 per cent.; transitionals, 6 per cent.; neutrophil myelocytes, 8 per cent.; large hyalines, 1 per cent. It will be seen that the red count remains the same, but the white cells have increased from 3300 to 10,600 per c.mm. On Dec. 4th 40 g. of galactose were given, and 3·69 g. of sugar were passed in the urine during the first three hours. The blood-sugar rose from its fasting level of 0·055 per cent. to 0·08 per cent. one hour, and 0·111 per cent. two hours after galactose.

Pathological report on spleen.—"Typical spleen of venous obstruction. The veins are greatly enlarged and thick-walled. Throughout the pulp the venous spaces are dilated and surrounded by fibrous tissue. Malpighian bodies small. No sign of streptothrix seen." Immediately after its removal an attempt was made by Dr. Leonard Colebrook to obtain a culture from the spleen of the streptothrix suggested by Alexander Gibson, of Oxford, as a possible cause of splenic anæmia, but the result was negative.

The patient was discharged on Dec. 5th and is making good progress.

Cases of complete cure of splenic anæmia after splenectomy have been recorded in the literature, but the operation must be performed in the very earliest stages, before the liver becomes involved. The prognosis becomes progressively more serious with the onset and advance of hepatic cirrhosis and, moreover, removal of the spleen in such cases does not prevent the gradual spread of the degenerative changes in the liver cells. Notwithstanding this, however, the spleen should be removed as soon as possible after the diagnosis has been made, if liver-tolerance tests show that hepatic efficiency is not much impaired, the reason for this being that the expectation of life is much greater after successful operation. In the early stages of splenic anæmia splenectomy is a relatively simple matter, for there is not much enlargement of the spleen and comparatively few adhesions; in the later stages the operation is a long and difficult one, and the operative mortality is heavy. It is essential also to remember that chloroform as an anæsthetic is contra-indicated in splenectomy if the liver function is in any way impaired.

The longer the physician hesitates before calling in a surgeon the less chance will the patient have of recovery. The diagnosis should be made as soon as possible, and no effort on the part of the practitioner should be spared to persuade the patient to undergo early operation. Having done this his responsibility ceases, but it is unfair to the surgeon and still less fair to the patient to delay consideration of splenectomy until the liver has undergone degenerative changes and the operative risk has become serious.

COMPLICATIONS OF TONSILLECTOMY IN CHILDHOOD.

BY A. G. OGILVIE, M.B. DURH.,
MEDICAL REGISTRAR, ROYAL VICTORIA INFIRMARY, NEWCASTLE-ON-TYNE; LATE HOUSE PHYSICIAN, HOSPITAL FOR SICK CHILDREN, GREAT ORMOND-STREET, LONDON.

TONSILLECTOMY is now firmly established as a valuable prophylactic and therapeutic measure, and is more widely advocated and performed at the present time than ever before. It has therefore seemed well to undertake a brief clinical review of such complications as occur, and to discuss their course and prognosis. The very infrequency, relatively speaking, of these illnesses gives point to such an investigation, as in ordinary practice personal experience of uncommon conditions naturally grows slowly, while few general clinical reviews of this subject have appeared in this country.

This paper is based on the in-patient records of the Hospital for Sick Children, Great Ormond-street. At that hospital over 5000 cases are operated on every year by the method of dissection introduced by Mr. G. E. Waugh. This method produces more satisfactory results than any other, as is now generally recognised. A very considerable proportion of the cases of complication included here, about half, had been operated on elsewhere by various methods. The years 1922 to 1927 inclusive were chosen as being the most useful, as it is only recently that the operation has been performed so extensively all over the country.

Nature and Incidence of the Complications.

It is first of all necessary to define the term "complication of tonsillectomy." An illness has here been accepted as a complication which quite definitely has begun within 24 hours of operation, whether its onset be insidious or abrupt; it must be severe enough to confine the child to bed for 24 hours or longer. When the operation has been undertaken for the relief of a disease already present any exacerbation of the illness occurring within 24 hours of operation is accepted as a complication. It is believed that this criterion is sufficiently accurate for the purpose.

No statistical conclusions are given as it is not claimed that every case of complication admitted to the hospital in the six years under review has been traced. In addition, very many of the cases were not operated on at the Hospital for Sick Children. The cases of complication following tonsillectomy which are seen from time to time in the wards of a children's hospital are apt to impress one unduly with their apparent frequency. A series of cases of post-tonsillectomy pneumonia seen shortly before this investigation was begun had created such an impression in my mind, but a careful search through the records revealed the real rarity of such cases together with the fact that they, like others, tend to occur in "runs."

The very fact that both physicians and surgeons can recall off-hand two or three complications of tonsillectomy, with dates, names, and details, supports this view. It is the rarity that stands out most clearly in one's memory.

The conclusion to which this investigation has led, therefore, is that tonsillectomy, performed according to Waugh's method, is a safe operation, though complications occasionally occur which may be serious, and rarely are fatal. It will be seen that the prognosis of these illnesses is usually good, recovery in the great majority of cases being rapid and complete.

It will suffice to indicate the course which complicated cases may be expected to follow, and the developments which may occur and should be watched for.

The *milder complications* are the most frequent. Surgical shock, always slight in this series, ketosis with occasional transient glycosuria, tachycardia, cervical adenitis, feverish cold, and post-tonsillectomy debility are included in this group. These cases all do well and give rise to little or no anxiety. Abscess very occasionally results from cervical adenitis (one case in this series) and a stay at a convalescent home may be necessary to cure post-operative debility; but the overwhelming majority, though ill enough to be kept in bed for a few days, make a complete recovery within 72 hours. Most of these illnesses follow directly on the operation, but an interval of 24 hours may elapse. A word may be added with regard to tachycardia. The condition is rare, but quite definite; the children are not shocked and appear quite well; ketosis is absent or very slight; and the temperature is normal except perhaps the first day. A pulse of 150–200 may be maintained for five to seven days, falling to normal by rapid lysis. Possibly this is a sympathetic effect. It must be understood, of course, that the discovery of ketones in the urine, or the general picture of shock or debility, does not absolve the practitioner from a search for evidence of more serious mischief. This will be mentioned again later.

There are a number of complications of slightly more serious import which may be discussed together. This group includes hæmorrhage, hysterical manifestations, acute gastro-enteritis, and otitis media. Primary hæmorrhage seems to be more important than secondary hæmorrhage, which was always mild and easily checked, but the majority of all cases are readily controlled by adequate treatment and do not require to stay in hospital longer than a week. One child, a boy aged 5, after a moderately severe primary hæmorrhage, passed obvious blood in the stools for nearly three weeks afterwards, but was never seriously ill. One death occurred.

The child who died was a girl of 3½ who was believed to be a case of so-called pseudo-hæmophilia. Her sister suffered from a similar condition and also died of hæmorrhage. The case was therefore thoroughly investigated.

Willebrand[1] has described a family with 23 bleeders in 66 members in four generations. The coagulation time is normal, but the bleeding time greatly prolonged. The platelets were down to 55,000 in some cases, though normal in others, but a purpuric tendency was definite in all.

Secondary Anæmia.—Certain cases of secondary anæmia of varying degree may be mentioned here. These all followed post-operative hæmorrhage, but comprised only a small proportion of the hæmorrhage cases. It is believed that these are cases of post-operative debility, complicated at the beginning by hæmorrhage. The red blood corpuscles are only moderately reduced, 3,500,000 to 4,000,000 per c.mm. being a usual figure. The main feature is the marked reduction of the hæmoglobin, which is often below 20 per cent. The anæmia is readily cured by the administration of iron, but the debility often necessitates a month or so at a convalescent home.

Hysterical manifestations, which here include chorea, are occasional and transient, and resolve completely. Cases of persistent vomiting without ketosis or other cause, dysphagia, and anorexia occurred, and all the patients were discharged cured within a fortnight. Special mention may be made of chorea. It is a striking fact that in the six years covered by this article only one case of chorea could be attributed to tonsillectomy, and this was discharged cured in seven weeks; while of a large number of established cases of chorea operated upon only one was made worse by tonsillectomy, and that only temporarily. Most were definitely improved by the operation.

Acute gastro-enteritis is rare, and rapidly cured. The onset may be with meningismus and fever. This may, however, occur as a secondary manifestation of *otitis media*, or other infection. Otitis media itself must receive special attention. The cases here discussed were admitted six to eight days after operation, because they were "not doing well." Aural discharge occurred on the day of admission, or the day after, in cases where myringotomy was not performed on admission. The prognosis was good, the discharge ceasing completely in two or three weeks, though occasionally a mastoid abscess followed. All the cases did well, and no case of cerebral abscess or meningitis occurred. This is decidedly one of the commoner complications.

Renal Complications.—Acute hæmorrhagic nephritis is the typical lesion, and ten such cases occurred in the period under discussion. The onset is sudden, with fever and general malaise, and occurs seven to ten days after operation. The interval after operation is not one of perfect health, the clinical picture suggesting slight post-operative debility and comprising lassitude and poor appetite. Occasionally the nephritis is merely a manifestation of a general septicæmia, and the prognosis is the prognosis of the graver condition. In uncomplicated cases the prognosis is excellent, as is typical of this illness generally. The blood-urea is not high (27–35 mg. per 100 c.cm.), and recovery is complete. One case remained in hospital nine weeks before the urine was reported clear, but this was exceptional. Two to three weeks was the usual period.

Pyelitis did not occur in this series, though one case of chronic parenchymatous nephritis, in which an exacerbation was induced by tonsillectomy, had blood and pus in the urine for ten days or so. This patient made a good recovery, and was discharged free of œdema and albuminuria; such exacerbations were uncommon. Cervical adenitis preceded the onset in one case by two days.

Septicæmia (*Septico-pyæmia*) is a grave complication, of which six examples were found. The children were "unwell" following operation for two or three days, this interval being followed by a sudden rise of temperature to 103° or 104° F., and the rapid development of an urgent illness. A feature of these cases was the early development of multiple local manifestations such as hæmorrhagic nephritis, otitis media, lobar or broncho-pneumonia, and empyema. In only one case were local manifestations absent, and it is of interest that this case comprised the only death in this group, the illness lasting 48 hours only. The development of local manifestations, therefore, however alarming in themselves, may be taken as by no means so alarming a feature in considering prognosis. Recovery in the five cases mentioned was complete in four or five months, only one patient having a trace of albumin in the urine on discharge. Pneumococci were grown from the blood in three cases, and in the remaining cases streptococci were grown from the urine during life, and in the fatal case from the heart's blood also.

Pulmonary complications were various, but the commonest were lobar pneumonia and bronchitis. Twelve cases of pneumonia and 21 cases of bronchitis occurred in this series.

Cases of lobar pneumonia were admitted, or readmitted, either directly after operation or within 48 hours. The result was uniformly good, the temperature falling by crisis on the third, fourth, or fifth day. Only one case of delayed resolution was discovered. The illness generally was always shorter

Willebrand, E. A. von: Finska Läksällsk. Handl., Helsingfors, 1926, lxviii., 87 (abstract of paper: Amer. Jour. Dis. Child., 1926, xxxii., 763).

and milder than ordinary lobar pneumonia, and the question arises as to whether these cases are true pneumonia at all. It is likely that different factors operate in different cases. Some are probably cases of bronchitis or mild blood infection associated with partial collapse of one lobe due to inhaled blood-clot; others may be ether pneumonias, while others again are almost certainly true lobar pneumonia. The part played by chill is difficult to assess, but it is worthy of note that nearly as many cases occurred following operations performed in the six summer months as in the winter and early spring.

Secondary complications of pneumonia occasionally occurred. A few cases of otitis media and two of empyema were noted. Other cases with multiple complications were really septicæmias, the pneumonia being as much secondary to the blood infection as the other manifestations. Broncho-pneumonia is unusual, only two cases apart from septicæmia being observed.

One of these followed directly on operation, and this case recovered completely in three weeks. The other, which was referred from outside, had evidently been operated on in the prodromal stage of measles. The child, a girl of 3½, was admitted three days after operation, exceedingly ill, with extensive broncho-pneumonia and an early measles rash. This child died after an illness of eight days. The part played by operation is difficult to state fairly, but one may say that the operation was prejudicial to the health of the child under the circumstances.

This case is a useful reminder of the necessity of reconsidering every case immediately before operation. A slight rise of temperature, with mild symptoms of disturbed health, ought to cause either the postponement of the operation or careful reconsideration of the case.

Bronchitis was frequent, uniformly mild, and nearly always rapidly and completely recovered from. It usually followed directly on the operation, and a week at most sufficed for cure. The most important point in this connexion is the occurrence of bronchiectasis. Contrary to what was expected, only one case of bronchiectasis could be attributed to tonsillectomy in six years.

This child had a history of bronchitis following operation which was slow in clearing, and which was followed by further attacks at intervals of several weeks, until admission three months after operation. There was then an established bronchiectasis and the child, a boy aged 2¼, died of a terminal septic broncho-pneumonia two months after admission. Both lungs were extensively involved. Bronchitis following tonsillectomy should clear rapidly, and any case which is slow in recovering may be suspected.

No case of pulmonary abscess was found. This complication is common in America though rare in this country. The use of local anæsthesia for tonsillectomy, which is popular in the United States, has been blamed for this, and with some reason.[2] There were six cases of empyema. In two of these no history of pneumonia was obtained, the only symptoms being those of "debility," with right shoulder pain in one case. One of these was a mixed pneumococcal and *Bacillus proteus* infection, and the other was streptococcal. Two cases were secondary to septicæmia, while two followed pneumonia. These were all pneumococcal. The prognosis may be regarded as good, more especially when one considers the uncertain outlook in cases of empyema in childhood generally. All these cases were treated by rib resection and drainage, and all were dry and healed inside four weeks with full expansion of the lung.

Acute Specific Fevers.—Two possible cases occurred, one of diphtheria and one of scarlet fever. The case of diphtheria followed directly on tonsillectomy, while the other began two days after operation, being diagnosed two days later. The relation of these cases to the operation may be denied, as both might be due to coincidence, but they are mentioned to illustrate the rarity of these illnesses after tonsillectomy, these being the only two in six years. It is, of course, possible that cases might be referred direct to a fever hospital, but it is unlikely that this would apply to more than half of them. It is worthy of special note that no case of post-diphtheritic palsy following tonsillectomy was reported at the Hospital for Sick Children in the six years under discussion.

Commentary.

If the condition of a child within 24 hours of operation is not satisfactory we know first of all that this may be due to hæmorrhage, surgical shock, or ketosis. Any one or more of these may be present, but even so, search should be made for evidence of other more important complications which may coexist at this stage. The temperature, pulse, and respiration may suggest pneumonia, and lead to an examination of the chest for evidence of this or of bronchitis, although a negative result cannot exclude either.

Pyrexia, without evidence of any of the above, suggests a close watch for evidence of scarlet fever or diphtheria, and an examination of the mouth for Koplik's spots, this last more especially in the presence of acute coryza. Even if these illnesses are incidental only, they are nevertheless important to detect. As a last resort, post-tonsillectomy intoxication may explain the symptoms, and is a relatively common condition. Such conditions as shock, ketosis, and post-tonsillectomy intoxication improve rapidly under treatment, as we have seen, and should such improvement not occur, it is an indication for a re-examination of the chest for signs of pulmonary involvement. We know that otitis media, nephritis, and septicæmia are unlikely to provide evidence of their presence so early, but an examination of the ears and the urine is wise; while a high temperature with a decided change for the worse suggests septicæmia, and it is useful to remember in such a case that nephritis, pneumonia, and otitis media may all be secondary manifestations of this condition. The significance of cervical adenitis as a possible forerunner of acute nephritis may be helpful.

The next case for consideration is that of a child who has perhaps apparently recovered fairly well from the operation, but who is brought by his parents two to ten days after because he has been listless, irritable, and has refused his food, and has generally "not been doing well." The temperature will almost certainly be raised, perhaps to 99° or 100° F., perhaps higher. The operation wound may be dirty, probably with enlargement of the cervical glands, and this may be the explanation of the symptoms. Other complications, however, may occur at this stage, and these have to be excluded. Three investigations are here of first-rate importance—examination of the ears for acute otitis media; of the urine for blood, albumin, and casts; and of the chest for established pneumonia or early empyema. The possibility of septicæmia is again to be considered, with aural, renal, and pulmonary complications as local manifestations, though usually the high swinging fever with the rapid development of an urgent illness suggests the diagnosis. A blood culture may settle the question. In otitis media watch should be kept, as always in this condition, for the development of a mastoid abscess.

Considering the evidence of the cases previously quoted, a prognosis given at any time during the period just considered may justifiably be favourable, except in septicæmia where it must be guarded. This is assuming that no grave unforeseen development has occurred, when the prognosis must of necessity be modified.

Lastly, a child may be brought up for advice several weeks or even months after tonsillectomy with a history of ill-health dating from the operation. The most likely causes of such a history, assuming that we are satisfied of its connexion with the operation, are a developing bronchiectasis, perhaps with septic broncho-pneumonia, an overlooked empyema, chronic aural infection with possible mastoid involvement, or post-tonsillectomy debility with or without some degree of secondary anæmia. Subacute nephritis is rare, no case occurring in the present series, but can be excluded by a routine examination of the urine.

A definite history of bronchitis following an operation with frequent recurrent attacks since suggests developing bronchiectasis, or at least an examination of the chest. Empyema, however, may give rise to no symptoms beyond debility and some shortness of breath on exertion, and therefore examination of the lungs must be routine in these cases in any event. The ears will yield definite positive or negative information, and the slightest mastoid tenderness is significant. These cases, however, are uncommon. The prognosis of empyema appears to be favourable, as previously stated, but bronchiectasis as always is of grave significance. The only case in this series died five months after operation. No case of chronic aural infection was noted, but cases do occur, and their course is apparently much the same as is usual in this condition—namely, tedious and uncertain. As has previously been mentioned, the series contains no case of post-diphtheritic paralysis. This is of interest, as it is still widely held that this is one of the risks of the operation. That these cases occur is not here questioned. It is, however, contended that the danger has been very greatly exaggerated.

---

[2] Ochsner, A., and Nesbitt, W.: Arch. Otolaryng., 1927, vi., 330.

It is hoped that this account of certain of the complications which may follow tonsillectomy will be helpful. The conclusion to which one must come on the evidence they supply is that not more than 1 in 200 cases of tonsillectomy suffers any ill-effects serious enough to confine the patient to bed as a result of the operation. Of these the majority are mild and readily overcome. The more serious complications are septicæmia, nephritis, and pneumonia, and may be expected within a week or ten days of operation, exceptions to this rule being bronchiectasis and empyema.

I wish to thank the honorary medical and surgical staff of the Hospital for Sick Children, Great Ormond-street, for kindly allowing me to make use of the records of the hospital.

NEW VIEWS ON THE TREATMENT OF HYPERTHYROIDISM WITH IODINE.

BY LUCIEN DAUTREBANDE, M.D., PH.D. EDIN.,
FONDATION REINE-ELISABETH, HÔPITAL BRUGMANN, BRUSSELS.

FEW methods of treatment have, at varying times, met with more changes of fortune than that of treating hyperthyroidism with iodine. Even though Coindet, as early as 1820, announced that he had discovered a new remedy for goitre in the iodine of certain kinds of seaweed, the treatment was practically abandoned until Trousseau, by chance, obtained proof of its favourable effects. He was called upon to treat a patient suffering from typical exophthalmic goitre whose pulse was particularly unsteady and rapid. Remembering that, while he might prescribe tincture of digitalis he must beware of iodine, by mistake he actually ordered several drops of iodine daily. Great was his astonishment when, a fortnight later, the patient returned to report that he had put on weight, was less nervous, had a much slower pulse, and was lauding the merits of tincture of iodine.

Up till about 1900 iodine was prescribed more and more for all forms of goitre, but from 1900 to 1912 the popularity of its use was greatly lessened by Kocher, who showed that colloid goitre with indurated nodules, or true adenomatous goitre, might present the symptoms of hyperthyroidism after the administration of iodine, although the patients had shown no trace of them beforehand. This syndrome was named "Iod-Basedow" by Kocher, and its demonstration was in great part responsible for the disfavour into which iodine fell in 1910. From 1910 to 1920 various workers (Marine and Lenhart, Chvostek, Marcel Labbé, Neisser, Neisser and Loewy, Zondek) reinvestigated the question, and showed by the records of some of their clinical observations that great benefit could be derived from the use of iodine in true exophthalmic goitre. Plummer, in 1923, published statistics of 400 cases, definitely establishing the value of iodine in the acute crises of exophthalmic goitre, and its value in the prevention of post-operative accidents. These facts were confirmed by numerous authors (Biedl and Redisch, Boothby, Fraser, Jackson, Mason, Mayo and Boothby, Means and his co-workers, Merke, Read, J. Slosse, Sturgie, &c.) The American workers, however, made two reservations; while all of them agreed in extolling the use of iodine in true exophthalmic goitre, they admitted its bad influence in patients with thyreotoxic adenoma, which the work of Plummer, as is known, had identified with the condition described by Kocher as Iod-Basedow.[1] If, according to the general opinion, iodine had an unusually rapid and efficacious action in exophthalmic goitre, the action was described as being essentially transient. It ceased, according to the majority of workers, immediately upon the stoppage of the drug. A second course of iodine could not have the same effect as the first, and certainly a third was, for the greater part, ineffective. In short, the action of iodine would stop if it were given continuously in the same dose as the initial one.

Favourable Results of Iodine Therapy in Thyreotoxic Adenoma.

Recent research by Dautrebande and Lemort[2] calls in question the two conclusions propounded by most of the writers previously quoted, concerning the nefarious influence of iodine in toxic adenoma and the shortness of duration of the therapeutic action of this drug. Dautrebande and Lemort have endeavoured to prove, by means of repeated examination of metabolism, whether iodine acts specifically on Basedow's syndrome only, or if favourable results can also be obtained in simple thyreotoxic adenoma. Their examinations were very numerous—ranging between 18 and 60 determinations of metabolism on each patient with toxic adenoma, and their conclusions are definite. They find that (in doses which will presently be stated) the administration of iodine has never produced an increase of the basal metabolism or of the symptoms as compared with their initial state, but has, on the contrary, the same beneficial action as in cases exhibiting Basedow's syndrome. This opinion was contrary to the conclusions of the Americans. Although we were alone in enunciating it at the time (Marcel Labbé has since supported our view[3]) in the face of the clearness of our results we could not but take our stand.

Boothby, the principal supporter of the opposite theory, writes: "Iodine administered to a case of toxic adenoma is fatal after ten days." The first thought of the reader confronted with the two theories is to ascribe to geographical differences the varying manner in which toxic adenomata react to iodine. Moreover, the condition known as Iod-Basedow still exists in Switzerland, and de Quervain avers that one daily comes in contact there with cases of goitre manifesting an individual intolerance to the drug however administered and in whatever dose above ½ mg. per diem—an intolerance which may induce the most advanced degree of cachexia if one fails to recognise its cause.[4] In the face of these contradictory conclusions, and before expressing a definite opinion, it will obviously be necessary to compare results obtained in countries where endemic goitre exists with the facts observed in flat countries. Be that as it may, the mere fact that iodine has a favourable action in Belgium in cases of thyreotoxic adenoma which are clinically identical with the toxic adenomata described by Plummer calls for reconsideration of one of the principal conclusions drawn from the American findings. The demonstration of the activity of iodine in the hyperthyroidism of toxic adenoma in which the thyroxin is, according to Plummer, normal, certainly weakens the most widely accepted explanation of the action of iodine in cases of Graves's disease—viz., that iodine re-establishes the normal iodine-saturation of the thyroxin, supposed to be desaturated in this affection.

[3] Bull. de la Soc. des Hôp. de Paris, July, 1928.

[4] In the Schweiz. Med. Woch., 1928, No. 1, will be found the most recent statistics on *Iod-Basedow in Switzerland*, reported by W. Fluck, and based on the most extended findings published to date.

The Duration of Action of Iodine.

The second general conclusion which seems to us to require amendment is that of the shortness of duration of the action of iodine. Up to the present iodine has been considered as a medicament with a momentary potent action which, employed up to the time of surgical interference, reduces considerably the operative mortality-rate in cases of Graves's disease to the very lowest figure (Mayo and Boothby: 0·96 per cent.), but is of no use as a fundamental treatment. Lemort and I have found that, by modifying the mode of administration of the drug, it is possible to get prolonged effects from the use of Lugol's solution.[5] The outstanding point in our technique is that we give iodine in continuous progressive doses. For a few days the patient is given 10 to 20 drops of Lugol's iodine daily, and as soon as the general condition has improved and the basal metabolism has fallen, we keep the patient under the initial dose of iodine, avoiding interruption in treatment (no matter of how short duration) as far as possible. The continued use of iodine, on the whole, has only a transitory result if one continues with the initial dose; in order, therefore, to keep the body exchanges and the clinical signs of hyperthyroidism at their minimum, we augment the dose of iodine each time the basal metabolism rises. By means of this technique we obtain a fall in the basal metabolism at each augmentation of the dose in 76 per cent. of cases of true exophthalmic goitre, and in 79 per cent. of cases of thyreotoxic adenoma. It therefore seems difficult to admit that iodine administered over a prolonged period encourages hyperthyroidism. We take the basal metabolism as an index of the amelioration of the disease, because of the objectivity of this biological method. All the clinical signs improved concurrently with the metabolism in cases of Graves's disease, and with a delay of some weeks in thyreotoxic adenoma.

Our method has this considerable advantage over the American method of a single dose administered during the few days before operation: by maintaining the metabolism at a minimum for a long time the patient is able to put on weight, and the operation can be carried out under the best possible physical conditions. All our patients have submitted to long preparation for operation (in some cases three to four months) and some were not operated on until they had put on 6, 7, 8, or 10 kg., and until the cardiac rhythm had become stabilised over a long period. Further, some of our patients maintained a minimum metabolism over a very long period with very small doses which is a great advantage for cases of hyperthyroidism who fear operation or who wish to put it off. (We have under observation patients who will presently have been treated by iodine for as long as three years, in the hope that it will not be necessary to operate.) On the other hand, this progressive method of dosage has enabled us, up to the present, to check the effects of prolonged hyperthyroid crises, some of which appeared alarming. Perhaps this treatment will go towards furthering the results obtainable from radiotherapy.

New Method of Administration of Iodine.

The method of administration of iodine seems to be important. As soon as the dose exceeds 20 drops a day, it is well to divide it into two, three, or four doses daily. As a matter of fact, iodine is eliminated with great rapidity (50 per cent. being found in the urine 12 hours after ingestion (Potel)). At present I am more and more inclined towards splitting the doses into fractions, and the two cases reported below show that that technique gives interesting results, and allows of a fall in metabolism in cases where simply increasing the dose has not been efficacious. The first case was a patient with true exophthalmic goitre, and the second a typical case of toxic adenoma.

CASE 1.—A single woman of 24 showed no hereditary tendency. In her previous history the only thing of note was frequent sore-throat. Her present illness had started without known cause two years previously. At the onset she noticed constant general lassitude, tremulousness, palpitation, headaches, and loss of weight. At the beginning of 1928 she was for a short time in hospital where a diagnosis of exophthalmic goitre was made and she was subjected to ten treatments by radiotherapy. For four months she had not menstruated. When admitted, on July 12th, 1928, to the care of Prof. Nolf, the classic signs of exophthalmic goitre were striking: marked exophthalmos with glittering eyes and fixed stare; extremely marked tremor of the hands, forearms, and eyelids; profuse sweating, and constant tachycardia with reduplication of the second heart sound. The arterial tension was 10/7 with an oscillometric index of 1½; œdema of the ankles was present, and there was persistent diarrhœa (four to five stools daily for several weeks). Attention has previously been drawn to the frequency of pharyngitis (in my first paper, loc. cit.) which is seldom absent in our country, whereas in America it is scarcely ever found. It was present in this patient with extreme and diffuse redness of the soft palate and the back of the throat. The thyroid was markedly enlarged on both sides, being of a hard elastic consistency. Its surface, though not completely uniform, did not present any clearly defined nodules, and over the entire extent of the thyroid a blowing murmur and a thrill were present. The most outstanding feature was extreme nervousness, which indeed was so uncontrollable that it was impossible to do a determination of the basal metabolic rate.

On July 15th, 1928, three 10-drop doses of Lugol's iodine were commenced daily, and on the 18th three 15-drop doses. On the 24th she was given three 25-drop doses, but the hoped-for improvement did not take place. On the 30th, after a day or two of relative quiet, we succeeded in doing two determinations of the basal metabolism at an hour's interval, the results being +76 per cent. and +84 per cent. From August 1st three 30-drop doses per day were administered, and from the 3rd three 35-drop doses. The nervousness was still as great, and the diarrhœa had not diminished. Nevertheless, the blood pressure improved, being 14/9 and the oscillometric index 2½. The metabolism was hardly altered; it was +68 per cent. on August 8th and +78 per cent. on the 11th after three 45-drop doses per day since the 9th. On the 21st it was still +75 per cent. On the 21st and 22nd ten 10-drop doses were administered throughout the day. On the 23rd the basal metabolism was +40 per cent. The nervousness was unquestionably diminished, although the pulse remained at 123. After determining the metabolism, 20 5-drop doses of Lugol's solution per day were ordered but, as the result of an error in nursing, the patient was only given two 10-drop doses on the 23rd, and four 10-drop doses and one 30-drop dose on the 24th. The metabolism on the 25th was +65 per cent. From that day the patient, who was becoming less and less nervous and in whom there was a distinct subjective improvement (she was having at the most two stools per day), apportioned out her own doses of iodine, taking 5 drops 20 times a day at half-hourly intervals. From that time onward improvement was established. Examination on the 27th showed that the exophthalmos had practically disappeared; the tremor was almost imperceptible, the patient was very much calmer, and she had put on 7 kg. in weight since admission. The metabolism on August 28th was +35 per cent., and on Sept. 3rd it was +37 per cent. in spite of a temperature of 99·3° F. This patient was operated on on the 6th (thyroidectomy as complete as possible being performed; 50 g. of thyroid being removed from the right side, and 30 g. from the left side). On the day of operation 3 ampoules of a special preparation of iodine were injected[6]; then from Sept. 7th ten 6-drop doses were given. After operation she ran a normal course. On the 10th she had menstruated. From the 14th she was given five 6-drop doses. The basal metabolism was again +32 per cent. on the 20th, and from that day iodine administration was stopped. On Oct. 10th the metabolism was +60 per cent., and on the 30th it was +62 per cent.

---

[5] We used a solution containing iodine 10 and potassium iodide 20, to 100 of water.

[6] In the first days following operation it is preferable to give iodine in the form of intramuscular injection. Most patients operated on for goitre, as a matter of fact, tolerate iodine by the mouth poorly. Sometimes iodine administered in milk is tolerated better.

CASE 2.—A married woman, aged 40, was seen for the first time on March 20th, 1928. She had no hereditary tendency, and childhood and puberty had been normal. She had married when aged 22, and had her first child when 24. She noticed that after this confinement she suffered from general weakness for two or three years. Three years before coming under our observation she had rapidly lost weight to the extent of 10 kg. in a few months without apparent reason. The menopause came on a year before the time of observation, the patient at that time having twice had a complete month of meteorrhagia within four months. Gynæcological examination at that time revealed only a few small fibroids, which rapidly disappeared. About three months before observation the patient had suddenly felt considerably more nervous; in a few days sleep disappeared, and on Jan. 30th diarrhœa started and was still present (nine or ten stools daily). At the same time she noticed that her skin was becoming livid. She had lost 3 kg. in weight in the last three months.

On examination she presented a striking example of characteristic thyreotoxic adenoma. Her colour was pale and dull, the thyroid was small and uniformly studded over *with little hard nodules; no blowing murmur or thrill* and no carotid pulsation were present. The pulse-rate was 128, and the pulse was regular in rhythm but not in force. The arterial pressure was 14/6·5, and the oscillometric index 3. The hæmoglobin was only 70 per cent., but no abnormal blood-cells were present. In the upright position trembling was barely perceptible. The patient was, nevertheless, highly nervous, a nervousness peculiar to cases of toxic adenoma, which has been called by me *agitation inquiète*. The metabolism was +41 per cent.

From March 21st she took two 10-drop doses of Lugol's solution. Subjective improvement took place immediately, the patient sleeping better, and feeling less nervous. The metabolism on April 21st was +24 per cent. Iodine was now augmented to two 25-drop doses per day. The metabolism on May 4th was +20 per cent., even though the patient was more nervous and though the pulse-rate, which had been 102, had now risen to 110. Nervousness increased during the following days, in spite of the administration of three 15-drop doses per day, and on the 21st the patient's metabolism was +67 per cent. From that date the dose was split up into 13 3-drop doses per day. Improvement was rapid, all the subjective symptoms diminishing; diarrhœa disappeared; the skin regained its usual appearance, and there was no longer *agitation inquiète*. The thyroid diminished to the extent of becoming impalpable. On June 2nd the basal metabolism was −30 per cent., and on the 5th +10 per cent. She had put on 3 kg. in weight from the beginning of observation, even though all the treatment had been ambulatory.

Operation was performed on June 7th (subtotal thyroidectomy). The patient continued to take thyroid up to the 23rd and then stopped all medication. On the 26th all symptoms had disappeared and the basal metabolism was −42 per cent.; on the 28th it was −23 per cent. In November she had put on 10 kg. in weight and her basal metabolism was −34 per cent.

This method of small doses of iodine, frequently repeated, is obviously difficult to apply in hospital. It is not wise save in exceptional cases to entrust its application to a nurse; it is always preferable, if one is dealing with careful patients, to leave to them the work of fractioning-out the doses. Applied with scrupulous exactitude, this method renders a real service to the surgeon who wishes to operate with the minimum of danger, and to the physician who has to combat an acute hyperthyroid crisis. Even though certain goitres are obstinate to all treatment, it will be advisable to try this technique in cases of exophthalmic goitre or thyreotoxic adenoma which have not reacted, or have ceased to react to the single continued progressive dose.

Conclusions.

1. In Belgium cases of thyreotoxic adenoma react to iodine in the same manner as cases of true exophthalmic goitre.

2. The administration of continued progressive doses of iodine, in a certain number of cases, allows the basal metabolism to be maintained at a minimum over a prolonged period.

3. Fractioning of the doses of iodine has been found to be efficacious in cases obstinate to treatment by progressive doses.

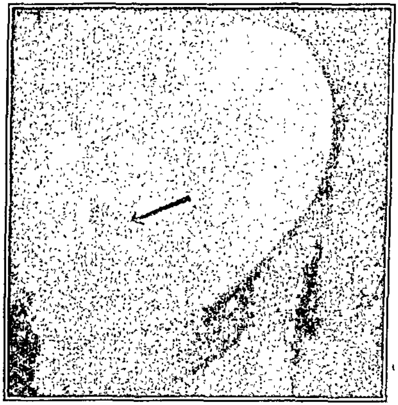
Clinical and Laboratory Notes.

A NOTE ON THE
PREOPERATIVE DIAGNOSIS OF DERMOID CYST OF THE OVARY.

BY ROBERT MAILER, M.D. EDIN., M.S. MINN., F.R.C.S. EDIN.,
HONORARY ASSISTANT SURGEON, VICTORIA INFIRMARY, GLASGOW.

ONLY very rarely is a dermoid cyst of the ovary definitely diagnosed before operation. Sometimes it is considered in the differential diagnosis of a swelling in the pelvis, but in the great majority of cases where a dermoid cyst has been revealed at operation the preoperative diagnosis has been uterine fibroid, simple ovarian cyst, or simply pelvic tumour. Marshall,[1] of the Mayo Foundation, reporting on a series of 415 cases of dermoid cyst of the ovary operated on at the Mayo Clinic up to the end of 1927, states that in no single case was the diagnosis made before operation, though since that time one or two cases have been recognised. In view of these facts the following case may be of interest.

The patient was a young unmarried woman of 20 under the care of Mr. R. B. Carslaw. She had complained of intermittent pain in the left lumbar region and in the left iliac fossa for ten years. Three years earlier she had had an attack of more severe left-sided pain resembling renal colic, and since that time she had suffered from menstrual irregularity and considerable premenstrual pain. Physical examination showed some tenderness in both iliac fossæ. Rectal examination was negative. An X ray photograph, taken to exclude calculus in the genito-urinary tract, revealed three small shadows on the left side of the pelvis apparently outside the bladder area. Their radial grouping, size, and shape did not suggest any relationship to the left ureter, and they bore a fair resemblance to the shadows of teeth. As the shadows overlay gas-filled bowel, a second photograph was taken after further bowel preparation, but the shadows remained constant. An unequivocal diagnosis was made of dermoid cyst of the left ovary containing three teeth. At operation (Mr. Carslaw) the diagnosis was confirmed, and a dermoid cyst the size of a tangerine orange, containing hair, sebaceous material, and three teeth was removed.



Radiogram showing the shadows above the brim of the pelvis.

[1] Marshall, J. M.: Proc. Staff Meetings, Mayo Clinic, 1928, iii., 4.

somewhat thin. The mitral valve showed patches of atheroma on the flaps and was relatively incompetent. The tricuspid valve was normal. The aortic valve cusps were somewhat thickened. The pulmonary valve was normal. The aorta showed extensive nodular atheroma throughout its whole length, but no rupture was found. The coronary orifices were surrounded by atheroma, but were nowhere obstructed; their lumen was rather wide, and there was marked atheroma of all the arteries. The pleural sacs had no adhesions or free fluid. The lungs were congested and collapsed at both bases. The liver and spleen showed marked cardiac congestion, but the pancreas was normal. The kidneys were somewhat swollen and fatty. In the intestines were numerous diverticula the size of peas distributed throughout the descending colon, sigmoid, and rectum.

It is interesting to try to picture the course of the lesion according to the symptoms displayed at various stages of the history—i.e., (1) originally, (2) early the next morning, (3) at noon, (4) on arrival at hospital, and (5) during the next night. It is also puzzling, in view of the autopsy notes, without any signs of infarct, to account for rupture of the auricle, especially without any exertion. The symptoms were never distressing enough to be diagnosed as anginal, and no one who saw the patient (including a cardiologist of repute) was able to get nearer the diagnosis than "cardiac." Probably the earlier symptoms were vagal, though the sudden ending and the absence of signs of hæmorrhage before it would seem to contra-indicate the probability of early leakage.

ROYAL SOCIETY OF MEDICINE.

TREATMENT BY COLLOID METALS.

AT a meeting of the Section of Tropical Diseases (to which members of two other sections had been invited), held on April 18th, Dr. J. B. CHRISTOPHERSON being in the chair, Sir LEONARD ROGERS communicated a paper by Prof. A. PALDROCK, of Tartu, dealing with his observations upon

Leprosy in Estonia and its Treatment by CO_2 Snow and Solganal.

The isolation of lepers, he said, still had its adherents, and at the present day it was compulsory in Estonia, but he doubted its utility, and thought it must yield to more humane methods. In the beginning of 1928 Estonia had 235 registered lepers, the numbers having remained fairly constant of late years. Of 236 cases in 1926, 127 were of the tuberose form, 26 of the macular, 36 of the anæsthetic, and 21 each of the tubercular anæsthetic and the macular anæsthetic. Most of the victims were agricultural labourers. The source of infection was traced to the mother 19 times, father 13 times, sisters 17 times, other relatives 20 times, and was unknown in 149 cases. The leprosy germs were situated chiefly in the lymph spaces; they consisted of several granules surrounded by a protective envelope, the whole being probably evident as a rod-shaped appearance. These granules generated other granules, and they in turn became centres of reproduction. From the rod-shaped fragments buds were seen to burst, and on the ends of the fragments were umbels. He considered that the germ of leprosy was not a bacillus, but a trichomyces or thread fungus. The granules were found to contain free nucleic acid, and in the envelope nucleo-proteins were present. Free lipoid was found chiefly in the envelope, lipoproteins being principally in the granules where the lipoid-albumin compounds were combined with a Gram-positive and with a Gram-negative lipoid acid.

Prof. Paldrock compared the micro-chemical behaviour of leprosy germs with that of tubercle bacilli. He had been able to show that lepers had free complement in their blood; the quantity of complement indeed might be greater than that of normal serum. This was all to the good in CO_2 treatment, which was accompanied by a measurable consumption of complement. If a leproma was congealed by CO_2 snow at minus 73° C. changes were thereby produced in colloid equilibrium; there was a movement of albuminoid to globulin, and thence on to fibrinogen. After freezing there was a change to plasma stability as manifested by an accelerated sedimentation velocity of the erythrocytes, an acceleration which was demonstrable for 14 days after the application of snow. Congealing at one sitting five to ten sites on a healthy skinned person with a CO_2 rod 5 mm. in thickness—as was done in leprosy treatment—was followed by considerable shock, in which there was a sudden drop in the leucocyte count. In lepers the extent of this drop depended on the duration of the disease. During the course of the treatment with the snow there was a continual increase in the leucocytes. The released products of the leproma became absorbed and distributed through the body, causing a resolution of uncongealed lepromata as a distant effect. Thus CO_2 snow was a means of active auto-immunisation, and the remedy was regarded as specific.

The application of local cold should, said Prof. Paldrock, be limited to the time necessary for provoking a disturbance of equilibrium in the leproma. It sufficed to press a CO_2 rod 5 mm. thick on a leproma of small diameter for three to four seconds. More than a fortnight was needed for the shock of the cold to work itself out; hence the application should be repeated in three to four weeks' time. Only five to ten lepromata should be treated at a single sitting; otherwise the degree of protein shock would be too great. Patients freed of their leprous symptoms could not be regarded as finally cured; in four-fifths of the cases there was, two years later, the recurrence of trunk lepromata of minute size; but these disappeared more quickly than the original lesions after a single application of the snow. Having been deprived of their envelope the granules became susceptible to the action of such chemotherapeutic remedies as had an affinity with the substances in the granules. Such a remedy was solganal, which contained 36·5 per cent. of gold. By means of this preparation the Gram-positive leprosy germs of the body were transformed into Gram-negative ones; it also exerted a specific effect on the leprosy germs. Ten per cent. solutions of solganal, up to a total of 11 to 13 g., were borne without trouble. A sign of the weakening of the germs was the fact that they gradually lost their acid-fastness.

If after two years of CO_2 treatment a tolerance for cold had been established, a new and different shock must be brought into use, and for this purpose solganal was appropriate, as it provoked the mobilisation of fresh protective forces against the already weakened micro-organism. It completed the work already begun by the snow.

Sir LEONARD ROGERS also read a communication by Dr. F. G. ROSE on a new method of obviating blockage of the veins in the

Intravenous Administration of Sodium Hydnocarpate

in leprosy. The method consisted in exposing the sodium hydnocarpate to the radiations of a mercury-vapour lamp. After this had been done the substance could be injected into smaller veins, and there was an absence of local irritation. If a small vein was chosen from the beginning the same vein could be used for the injections repeatedly, without causing any difficulty. Even small children tolerated the 3 per cent. solution. The radiation changed the colour of the solution from a light to a darker shade of yellow. To ascertain whether the radiation affected the activity of the drug controls were employed. Œdema of hands and forearms which somtimes followed the injections could be readily cleared away by applying evaporating lead lotion.

Dr. R. A. **HENDRY** said it did not yet seem clear that metals such as gold, mercury, and copper, in various forms, had a definite specific effect in the treatment of leprosy and tuberculosis. Of recent years attention had been chiefly centred on gold. Gold differed from most of the metals which had come into use as a result of chemotherapeutic work from the fact that it could not be combined directly with carbon; attempts had been made to combine gold with carbon through the intermediation of sulphur. He agreed that under the influence of CO_2 snow the metals might have a different action, but so far the results on the whole were disappointing.

Dermatological Experience.

Dr. **HALDIN DAVIS** said he had used certain gold compounds in lupus erythematosus, and to a limited extent in psoriasis. In 1913 Brook and Gluck used gold for lupus vulgaris, as a result of which they reported striking improvement, but not cure. Crysolgan was then largely used. In vitro it was found in a strength of one part in a million to restrain the growth of tubercle bacilli. In a series of 43 cases treated in this way 28 were cured, 6 were improved, 4 were in a stationary condition, 4 became worse. He thought these four had received an overdose. The drug which, in his experience, had been most useful in lupus erythematosus was sanocrysin, a combination of gold and thiosulphite. Lupus erythematosus seemed to him to have many affinities with tuberculosis, though it was still undecided whether it was a tuberculous manifestation or not. For the disease he was referring to, sanocrysin was, in his experience, more valuable than crysolgan. With regard to toxicity, 35 mg. of sanocrysin per kilo of body-weight was well borne by animals, so that a safe amount for a man of 120 lb. weight would be 2000 mg. Crysolgan was about half as toxic as sanocrysin. There were objections to the use of these drugs. After sanocrysin skin rashes were common, and after a small dose he had seen a pruritic rash on the arms and legs. These manifestations, however, were usually evanescent, and left no serious trouble. Stomatitis or ulceration of the tongue might occur. Dr. Drake had reported the occurrence of pustular eruptions in the scalp in a patient who was having sanocrysin for phthisis. The speaker had seen a case which after sanocrysin developed exfoliative dermatitis, causing the patient to be ill for a month. At the end of that time when the skin had recovered the lupus erythematosus was found to have disappeared entirely. The condition had lasted 16 years, and the patient had lost all her hair. Recently there had been a slight relapse, but a good new growth of hair persisted. In psoriasis the story of colloid metals was much the same as that of other drugs—namely, very unequal results.

Gold Salts in Tuberculosis.

Dr. F. G. **CHANDLER** spoke of the use of gold salts in the treatment of tuberculosis. In the last three or four years he had treated with sanocrysin 50 to 60 cases of pulmonary tuberculosis. At first large doses were given and severe reactions followed. At a later period he started with 0·1 g., increased to 0·25, 0·5, 0·75, and finally 1·0 g., until nine grammes had been given. He could not speak confidently about the therapeutic value of the drug, but he believed in its efficacy, and intended to persevere with it. After its use albuminuria was almost a constant feature, though, if slight, this might be practically ignored; but it was essential to examine the urine microscopically after each injection. If blood cells or casts were found the treatment was suspended until the urine became clear. Sometimes diarrhœa occurred, but it was ephemeral, and could usually be ignored. At the first sign of skin disease he stopped the drug and did not care to resume it. Vomiting might occur. Pain and sloughing might take place at the site of inoculation if any of the material were allowed to get outside the vein. He thought sufficient had been achieved to warrant a further exploitation of gold as a therapeutic agent in such diseases as leprosy and tuberculosis.

Dr. J. M. H. **MACLEOD** said that in his hospital department sanocrysin had been used a good deal, but he did not yet feel able to speak definitely as to results. He agreed, however, that better results had been obtained with sanocrysin than with crysolgan. Of 15 cases of lupus erythematosus under treatment a few had shown signs of improvement; in others the result so far was doubtful. He did not think there was any real connexion between this disease and tubercle; in many cases lupus erythematosus was associated causally with some septic focus. Some acute cases had reacted to the new B. W. & Co. antiscarlatinal vaccine. Probably a streptococcus was at the bottom of the trouble. No drug was yet known to have a specific effect on the tubercle bacillus, and he did not know of one which acted specifically and directly on the leprosy bacillus. With regard to freezing by CO_2 he spoke of his pioneer work with this method, and remarked that a three-second contact with a leprous lesion, under whatever pressure, did not seem likely to cause much result. If the organism responsible for leprosy were a streptothrix he did not understand the difficulty everybody experienced when trying to grow it. He thought the effect of irradiation on a colloid metal would be to render it inert.

Reply.

Sir **LEONARD ROGERS** said he had no personal experience of CO_2 in leprosy, but any method which would distribute a certain number of leprosy bacilli and set free antigens would produce some degree of immunity. The dose must be so regulated that no severe reactions followed, but it was only in certain early cases that the improvement went on long enough to clear the bacilli out. The method described by Prof. Paldrock was based, he thought, on the right principle. In some cases a simpler but efficacious method was to apply 25 per cent. trichlor-acetic acid. 5000 new cases of leprosy were now under treatment in various parts of the world, chiefly in Africa, and patients were returning week after week for their injections as they themselves believed in it.

SOCIETY OF MEDICAL OFFICERS OF HEALTH.

AT a meeting of this Society, held on April 19th, the chair was taken by Dr. J. **HOWARD-JONES**, the President, and a discussion on

BIRTH CONTROL

was opened by the Rev. **GRIFFITH JONES**. He spoke of the change of attitude towards this subject and of the falling birth-rate. In 50 years the birth-rate had decreased by more than half, and ours was now the lowest in Europe; within five years, at this progress, the birth-rate and death-rate would be equal. Man was on this planet, he thought, primarily to live his individual life to the highest possible extent and value for himself, and, secondly, to increase and improve his race by begetting healthy offspring. To these ends he was supplied with imperative instincts. Mr. Griffith Jones insisted that the "family instincts" were a set of organic instincts interlocked and combined into a group which was intended to remain a group and not to be separated into the components. The natural unit of society was the father-mother-and-child and not the husband-and-wife. Mankind was not endowed with sex propensities for their own sakes but purely as a means to an end, the production of offspring. Were it not for sex there would be no qualitative improvement at all, no upward movement from the amœba to man. Nearly all the beauty of nature was derived from some form of sexual attraction. For the perfect family relationship—so that every boy and every girl somewhat thin. The mitral valve showed patches of atheroma on the flaps and was relatively incompetent. The tricuspid valve was normal. The aortic valve cusps were somewhat thickened. The pulmonary valve was normal. The aorta showed extensive nodular atheroma throughout its whole length, but no rupture was found. The coronary orifices were surrounded by atheroma, but were nowhere obstructed; their lumen was rather wide, and there was marked atheroma of all the arteries. The pleural sacs had no adhesions or free fluid. The lungs were congested and collapsed at both bases. The liver and spleen showed marked cardiac congestion, but the pancreas was normal. The kidneys were somewhat swollen and fatty. In the intestines were numerous diverticula the size of peas distributed throughout the descending colon, sigmoid, and rectum.

It is interesting to try to picture the course of the lesion according to the symptoms displayed at various stages of the history—i.e., (1) originally, (2) early the next morning, (3) at noon, (4) on arrival at hospital, and (5) during the next night. It is also puzzling, in view of the autopsy notes, without any signs of infarct, to account for rupture of the auricle, especially without any exertion. The symptoms were never distressing enough to be diagnosed as anginal, and no one who saw the patient (including a cardiologist of repute) was able to get nearer the diagnosis than "cardiac." Probably the earlier symptoms were vagal, though the sudden ending and the absence of signs of hæmorrhage before it would seem to contra-indicate the probability of early leakage.

TREATMENT BY COLLOID METALS.

AT a meeting of the Section of Tropical Diseases (to which members of two other sections had been invited), held on April 18th, Dr. J. B. CHRISTOPHERSON being in the chair, Sir LEONARD ROGERS communicated a paper by Prof. A. PALDROCK, of Tartu, dealing with his observations upon

Leprosy in Estonia and its Treatment by CO_2 Snow and Solganal.

The isolation of lepers, he said, still had its adherents, and at the present day it was compulsory in Estonia, but he doubted its utility, and thought it must yield to more humane methods. In the beginning of 1928 Estonia had 235 registered lepers, the numbers having remained fairly constant of late years. Of 236 cases in 1926, 127 were of the tuberose form, 26 of the macular, 36 of the anæsthetic, and 21 each of the tubercular anæsthetic and the macular anæsthetic. Most of the victims were agricultural labourers. The source of infection was traced to the mother 19 times, father 13 times, sisters 17 times, other relatives 20 times, and was unknown in 149 cases. The leprosy germs were situated chiefly in the lymph spaces; they consisted of several granules surrounded by a protective envelope, the whole being probably evident as a rod-shaped appearance. These granules generated other granules, and they in turn became centres of reproduction. From the rod-shaped fragments buds were seen to burst, and on the ends of the fragments were umbels. He considered that the germ of leprosy was not a bacillus, but a trichomyces or thread fungus. The granules were found to contain free nucleic acid, and in the envelope nucleo-proteins were present. Free lipoid was found chiefly in the envelope, lipoproteins being principally in the granules where the lipoid-albumin compounds were combined with a Gram-positive and with a Gram-negative lipoid acid.

Prof. Paldrock compared the micro-chemical behaviour of leprosy germs with that of tubercle bacilli. He had been able to show that lepers had free complement in their blood; the quantity of complement indeed might be greater than that of normal serum. This was all to the good in CO_2 treatment, which was accompanied by a measurable consumption of complement. If a leproma was congealed by CO_2 snow at minus 73° C. changes were thereby produced in colloid equilibrium; there was a movement of albuminoid to globulin, and thence on to fibrinogen. After freezing there was a change to plasma stability as manifested by an accelerated sedimentation velocity of the erythrocytes, an acceleration which was demonstrable for 14 days after the application of snow. Congealing at one sitting five to ten sites on a healthy skinned person with a CO_2 rod 5 mm. in thickness—as was done in leprosy treatment—was followed by considerable shock, in which there was a sudden drop in the leucocyte count. In lepers the extent of this drop depended on the duration of the disease. During the course of the treatment with the snow there was a continual increase in the leucocytes. The released products of the leproma became absorbed and distributed through the body, causing a resolution of uncongealed lepromata as a distant effect. Thus CO_2 snow was a means of active auto-immunisation, and the remedy was regarded as specific.

The application of local cold should, said Prof. Paldrock, be limited to the time necessary for provoking a disturbance of equilibrium in the leproma. It sufficed to press a CO_2 rod 5 mm. thick on a leproma of small diameter for three to four seconds. More than a fortnight was needed for the shock of the cold to work itself out; hence the application should be repeated in three to four weeks' time. Only five to ten lepromata should be treated at a single sitting; otherwise the degree of protein shock would be too great. Patients freed of their leprous symptoms could not be regarded as finally cured; in four-fifths of the cases there was, two years later, the recurrence of trunk lepromata of minute size; but these disappeared more quickly than the original lesions after a single application of the snow. Having been deprived of their envelope the granules became susceptible to the action of such chemotherapeutic remedies as had an affinity with the substances in the granules. Such a remedy was solganal, which contained 36·5 per cent. of gold. By means of this preparation the Gram-positive leprosy germs of the body were transformed into Gram-negative ones; it also exerted a specific effect on the leprosy germs. Ten per cent. solutions of solganal, up to a total of 11 to 13 g., were borne without trouble. A sign of the weakening of the germs was the fact that they gradually lost their acid-fastness.

If after two years of CO_2 treatment a tolerance for cold had been established, a new and different shock must be brought into use, and for this purpose solganal was appropriate, as it provoked the mobilisation of fresh protective forces against the already weakened micro-organism. It completed the work already begun by the snow.

Sir LEONARD ROGERS also read a communication by Dr. F. G. ROSE on a new method of obviating blockage of the veins in the

Intravenous Administration of Sodium Hydnocarpate

in leprosy. The method consisted in exposing the sodium hydnocarpate to the radiations of a mercury-vapour lamp. After this had been done the substance could be injected into smaller veins, and there was an absence of local irritation. If a small vein was chosen from the beginning the same vein could be used for the injections repeatedly, without causing any difficulty. Even small children tolerated the 3 per cent. solution. The radiation changed the colour of the solution from a light to a darker shade of yellow. To ascertain whether the radiation affected the activity of the drug controls were employed. Œdema of hands and forearms which somtimes followed the injections could be readily cleared away by applying evaporating lead lotion.

it could be made to fit exactly. The Dumas was used for the very short cervix with lax vaginal walls unable to retain a Dutch cap. The most recent spermaticide was the Parke Davis 2-grain hypodermic tablet of quinine and urea hydrochloride which was placed within the concavity of the cap next the cervix. It was odourless and non-greasy, and the experience of 14 months showed that it was efficient enough to render the douche unnecessary. This was an important improvement on the "cap" method.

The records being accumulated by the clinic were very valuable, and it was hoped before long to be able to give an answer to several vexed questions. In judging results, facility and comfort in use must be considered as well as technical efficiency. Over 1600 patients had attended the clinic. In estimating results none was called "good" unless it was known positively that the method had been used for at least six months with comfort and success by a woman previously fertile. Of the first 50 patients at the clinic 29 showed good results, and among these there were eight failures for the following reasons: neglect to use the pessary (four); pelvic difficulties, neglect to syringe properly, nervousness, and habitual constipation (one each). The average wage among these families was £2–£3 a week. Among the first 100 women fitted with the latest developments, 59 reported good results for at least six months. There was one failure for no discoverable cause, one due to neglect of syringing, one to use of a broken pessary, and five from neglect to use the cap. No woman who subsequently wanted a baby had failed to have one on giving up the use of the contraceptive.

Mrs. HODGSON described a rural clinic experiment she had recently seen in California; the unit included an emergency ward and a room where advice was given on different days on infant welfare, tuberculosis, venereal disease, and therapeutic birth control. Very poor people of low mentality found present methods difficult to learn: it was to be hoped that some simpler way would be found for them.

Mr. GRIFFITH JONES briefly replied.

The PRESIDENT, in proposing a vote of thanks, observed that in his town the death-rate had exceeded the birth-rate during the whole of the first quarter of this year, though the deaths had not been remarkably numerous.

LIVERPOOL MEDICAL INSTITUTION.

At a pathological meeting of this institution on April 11th Mr. C. ALEXANDER WELLS read a paper on

Congenital Anomalies of the Ureter.

After referring briefly to the embryology, he described a series of cases in which he had prepared diagrams of the cystoscopic appearances and lantern slides from radiograms. These cases included five examples of reduplication of the ureter on one side, and he pointed out the importance of recognising this abnormality and of instituting adequate investigation in order to avoid mistakes in diagnosis, such, for instance, as passing an opaque catheter up a healthy ureter, some distance away from the doubtful stone shadow, when a second instrument passed along the second ureter on the same side would demonstrate its true nature. He briefly described the morbid anatomy of the kidney in these cases and, after passing rapidly over congenital cystic kidney, simple and crossed dystopia and unilateral absence of the kidney, spoke on the subjects of congenital dilatation of the ureter and ureterocele. He showed the cystoscopic and radiological findings in the case of a boy of three with enormous dilatation of both ureters, with their pelves and calices, without any demonstrable obstructive lesion—in fact, with widely patent ureteric orifices on both sides, conforming to [illegible] d though rare type. He further submitt[illegible] cases which he said were [illegible] segmental congenital dilatation of certain authors and described, in connexion with them, a reflux up the ureters of the contents of the bladder, synchronous with respiratory movements and indicated by the excursions of a flake of mucus. This sign he suggested was characteristic of a more or less dilated ureter plus a fixed patent orifice, and he said he had noticed it also in tuberculous infection of the ureter. The paper was concluded with two cases of ureterocele or ureteric balloon.

In the discussion which followed, Mr. FRANK JEANS spoke of the pitfalls associated with congenital absence or misplacements of one kidney. Dr. NORMAN CAPON referred to two cases of congenital dilatation of the bladder and ureters described by him some years ago in association with Dr. Fordyce. Mr. R. KENNON doubted the congenital nature of the segmental dilatations, and Mr. J. T. MORRISON referred to the difficulties of diagnosis due to disease complications of anatomical variations and described a case of calculus occurring in a ureterocele.

Reviews and Notices of Books.

PROTOZOOLOGY.

A Manual for Medical Men. By JOHN GORDON THOMSON, M.A., M.B., Ch.B., Director, Department of Protozoology, London School of Hygiene and Tropical Medicine; and ANDREW ROBERTSON, M.B., Ch.B., Lecturer and Milner Research Fellow in the Department of Protozoology. London: Baillière, Tindall and Cox. 1929. With four plates and 220 text-figures. Pp. xvi.+376. 30s.

DURING the past few years a number of books on the medical aspects of protozoology have been published, each having special features. This work occupies a place of its own. It is written expressly for medical men and deals largely but not entirely with those protozoa which are human parasites. Though each organism is fully described the general arrangement of the book is based on the disease-producing powers rather than on the zoological status, the pathology of the infections occupying a prominent place. For these reasons the order in which the parasites are presented to the reader is not that of the systematist, but rather that of the clinician or pathologist, the important malarial parasites occupying first place. However, sufficient attention is given to the allied parasites of animals to enable the student to realise that human beings are not the only hosts afflicted, and that the study of animal infections may at times throw considerable light on those of man.

The book begins with a short introduction which deals with such subjects as the structure of the cell, the methods of multiplication, and the classification of the protozoa. The reader is then introduced to the malarial parasites of man, of which the morphology, differentiation, life-history, transmission, cultivation, and pathology are described in about 60 pages, with a note on immunity and the complication of blackwater fever. There follows a short section on the allied parasites of animals. The account is clear and concise and the student who reads the section carefully will find in it all that he requires to know. It is noteworthy that the authors adopt the view that there are three well-known species in man and regard others which have been described as of doubtful authenticity. Attention is drawn to artefacts in blood films; various objects to be seen under a microscope are illustrated in a coloured plate, so that confusion may be avoided. A short section on coccidiosis includes an account of the notorious coccidia of fish which may be encountered in human fæces and which led to the erroneous assumption that they were human parasites. This is followed by sections [illegible] plasmosis, hæmogregarines, and the [illegible] Seventy pages are devoted to the [illegible] intestinal amœbæ of man, certain [illegible] and coprozoic amœbæ. The pathogenic *Entamœba histolytica* receives the same close attention as is accorded to malarial parasites. Under the heading flagellates are considered those which are parasitic in the intestine of man, the leishmania, and the allied trypanosomes. The section devoted to the intestinal forms is followed by a useful account of the methods of examination of fæces for protozoa and the common objects which may be encountered and may cause errors in diagnosis. As regards the leishmania, the recent work carried out with sand flies and the possibility of transmission of kala-azar and oriental sore by the agency of these flies is fully discussed. The section on the trypanosomes is sufficiently comprehensive and is followed by short accounts of the ciliates and the sarcosporidia. This completes the consideration of the protozoa, but certain intracellular bodies of doubtful nature, such as anaplasma, bartonella, rickettsia, and the undetermined toxoplasms are also described. Spirochætes, though admittedly not protozoa, are carefully and fully dealt with for the convenience of medical men. A section on technique as applied to the study of parasitic protozoa and a glossary of the derivations of certain names and terms complete the volume. The authors have caused Greek words to be written in Roman characters for the benefit of those who are unacquainted with Greek, but it seems to us doubtful if they will appreciate the change.

The work is beautifully got up and illustrated. Students at the London School of Hygiene and Tropical Medicine and similar teaching institutions, for whom the book was primarily written, are fortunate in having presented to them in such an attractive form the important facts of medical protozoology.

SURGERY.

Problems in Surgery. University of Washington Graduate Medical Lectures, 1927. By GEORGE W. CRILE, M.D. Edited by AMY F. ROWLAND. London and Philadelphia: W. B. Saunders Company, Ltd. 1928. Pp. 171. 18*s.*

IN this volume of collected graduate lectures Dr. Crile sets out interesting and original observations on half a dozen subjects. The first lecture on the management of the acute infections expresses orthodox views in a concise and attractive manner and the author's own epigram of "cut and quit" well illustrates his argument. In the lecture on malignant and premalignant conditions the use made in the Cleveland Clinic of Surgery, Radium, and X Rays is well summed up, and valuable statistics of results in the treatment of cancer are given. The third chapter, on operations on the bad-risk patient, contains the fruits of the work of Crile and his associates on shock and allied conditions. The use of diathermy to maintain the body temperature during and after operation is, so far as we are aware, new in this country, and merits trial; but we find it difficult to place as much faith in blood transfusion for bad-risk cases such as are not directly due to hæmorrhage as appears general in America. Of hyperthyroidism Dr. Crile writes with the immense experience of 17,759 operations on the thyroid gland behind him; he stresses the importance of the amount of tissue to be removed. The picture of the extreme case requiring almost total removal of the gland as "a temperamental young married woman, with a faithless husband, a sickly child, insufficient income, quarrelsome relatives, and infected tonsils" makes one admire, but with a tinge of regret, an operative mortality of 0·8 per cent.! The fifth lecture is a diagnostic and operative clinic on the surgery of the gall-bladder, stomach, and breast, and the final one deals with some of Dr. Crile's views on the body as a bipolar electric machine. This last chapter, while full of stimulating speculations and possibilities, takes so much for granted that it fails to be convincing, and we feel that the author will have difficulty in inducing acceptance of his doctrine that life consists fundamentally in the maintenance of a difference in potential. The book is admirably printed and illustrated and will provide many new ideas for the study of the critical reader. It must, however, be read with care because fact is not clearly separated from theory, and we can imagine that with Dr. Crile's personality behind these lectures the graduates who heard them may well have failed among the abundance of wheat to detect any chaff at all.

Surgery in the Tropics. By Sir FRANK POWELL CONNOR, D.S.O., F.R.C.S., D.T.M. & H., Lt.-Col. I.M.S., Professor of Surgery, Medical College of Bengal, Calcutta; and Surgeon to the College Hospital. London: J. and A. Churchill. 1929. Pp. 293. 12*s.* 6*d.*

THE author of this book prophesies that tropical diseases are likely to be distributed more widely now that aerial communication is becoming extensively used. Moreover the depressing effect of residence in a hot climate alters the whole outlook in surgical diseases, and thus arises the need for a book written by a surgeon actively engaged in practice in the tropics. On the whole Sir Frank Connor succeeds well in his attempt to write a supplement to the ordinary surgical text-book, bringing out the special methods found to be more effective under the conditions in which he lives and works. The novice plunged into tropical surgery would welcome rather more explicit directions as to treatment of such diseases as plague, which is dismissed in 16 lines, or Baghdad boil, for which the dose and frequency of administration of antimony tartrate is not given. The author's experience of the efficacy of intravenous iodine injections in septicæmic conditions including plague, and of the success of lymphangioplasty in elephantiasis is of especial interest since this operation has been abandoned in Europe. The management of ileostomy for intractable dysentery should receive fuller notice. The book is of small size and can usefully be added to the equipment of any practitioner proceeding to the tropics.

MATERNITY AND CHILD WELFARE. By ETHEL CASSIE, M.D., Ch.B., D.P.H. Edin. London: H. K. Lewis and Co., Ltd. 1929. Pp. 228. 8*s.* 6*d.*

DR. Cassie sets out to fill an obvious want by supplying health workers in maternity and child welfare with a book between the elementary type suited to voluntary and untrained helpers and the advanced type of little value to those without medical training. She has succeeded very well and has steered a straight course without much deviation to one side or the other. Here and there she has perhaps gone further afield into medical and scientific matters than will be appreciated by the audience she is catering for. Much of the chapter on embryology and related problems, particularly the attempt to discuss maturation and fertilisation of the ovum, transmission of hereditary factors by the chromosomes and Mendelian laws, will be found too condensed to be of any educational value to a health visitor.

The first of the three sections into which the book is divided is mainly taken up with the administrative duties of the health visitor—in the home, at the antenatal and infant clinic, and at special clinics and institutions. A chapter on the health visitor and the midwife may raise some resentment among midwives, for it begins by saying that the health visitor is often required to act as inspector of midwives, and its message appears to be addressed largely to those acting in this capacity. The better trained and experienced midwives are inclined to object to the inspector who has no more knowledge of midwifery than that acquired during training for the C.M.B. certificate. Unless she has had the responsibility and experience of having herself practised as a midwife she can neither appreciate the difficulties under which these workers carry out their duties, nor inspire in them that confidence which they ought to feel in a teacher and adviser.

Section II. is occupied with physiological and hygienic matters—infant feeding, food values, weaning and child management; and Section III. with pathological states—the premature, feeble, and ailing infants, metabolic disorders and infections, together with diseases of special sense organs, throat and nose, and mental deficiency. All of it will be of value to health workers.

Though in this book the matter is clearly set out and the teaching generally is sound, the whole lacks inspiration. Something is wanting to make the dry bones live; possibly it is more of the human side and a little humour. The paragraph headings of "The Hostile Grandmother" and "Interfering Neighbours" raised our hopes, but without justification. It is possible, however, that a lighter touch would not be appreciated by many of those who take their work most seriously, being sensible of its fundamental importance. Dr. Cassie has supplied a text-book which contains an adequate presentation of what a health visitor should know and will doubtless have many and grateful readers.

THE CONSTITUTION OF SUGARS.

By WALTER NORMAN HAYWORTH, D.Sc., Ph.D., F.R.S., Professor of Chemistry in the University of Birmingham. London: Edward Arnold and Co. 1929. Pp. 100. 8*s.* 6*d.*

THE discovery by Emil Fischer of two methyl glucoside derivatives of glucose led to the recognition of the fact that the ordinary open chain aldehyde form of glucose represents an intermediate form between two stereochemical α and β glucoses which had of necessity to possess a cyclic structure. The particular structure selected was that of a five-membered ring composed of four carbon atoms and one oxygen, though the possibility of alternative rings was not excluded. With the preparation by Purdie of the methylated sugars a new mode of investigating the nature of the heterocyclic ring was created, and by this means the St. Andrew's School, largely under the direction of Principal Irvine, did much to elucidate the inter-relationships between the various derivatives; it is, however, the merit of Haworth and his co-workers to have set the coping-stone upon this work by providing unequivocal proof as to the nature of the ring structure concerned. Basing upon these researches the author has suggested a new nomenclature, according to which pentoses and hexoses are to be termed respectively furanoses and pyranoses, in order that their relationship to the heterocyclic compounds furan and pyran shall be indicated in their names. This volume, which incorporates some of the manuscript prepared by the author for a course of lectures delivered at the Universities of Bâle, Zürich, Heidelberg, Neuchâtel, and Mulhouse, sets forth in simple language the brilliant reasoning and ingenious experimentation by means of which the constitutions of the sugars have been deduced. Those who have not had the opportunity of reading the original papers should be grateful to the author for having provided them with this lucid summary of our present knowledge of the constitution, not only of the monosaccharides, but of the di, tri, and polysaccharides as well.

EXPERIMENTELLE NEUROLOGIE.

Physiologie und Pathologie des Nervensystems. By E. A. SPIEGEL, Assistant in the Neurological Institute of the University of Vienna. Part I. With 69 illustrations. Berlin: S. Karger. 1928. Pp. 281. M.24.

DR. Spiegel believes there is a need for a comprehensive text-book dealing with experimental neurology, by which is understood not merely neurophysiology in a general sense but also experimental neuropathology, and he has undertaken to attempt to fill the gap. This first part of his text-book is certainly full of promise; it deals at the outset with general theories of neural function and proceeds to investigate reflectivity. At this point the studies interest the clinician, since reflex changes following different organic conditions are fully described. A second section deals in similar fashion with the vegetative nervous system. In this way the reader is given a précis of the anatomy, physiology, experimental pathology, and pathogenesis of mechanisms whose clinical function he studies in health and disease. A book of this kind is really useful.

LARYNGOLOGY AND NEUROLOGY.

Kehlkopf und Rachen in ihren Beziehungen zu den Erkrankungen des Zentralnervensystems. By Dr. BELA FREYSTADTL, Budapest. Berlin: S. Karger. 1928. Pp. 326.

DR. Freystadtl's monograph covers the field gleaned by the laryngologist on one side and the neurologist on the other. A review of this kind serves a useful purpose in linking up divergent studies; some 200 pages are allotted to a systematic description of the laryngeal features of disease of muscle, peripheral nerves, cord, brain-stem, and cerebrum. This is excellently arranged; much of the information here collected embodies rather out-of-the-way data of which it is helpful to be reminded. The laryngeal semiology of functional conditions such as hysteria, neurasthenia, and occupation neuroses is followed by a final section on laryngeal spasms and involuntary movements of various kinds, inclusive of so-called palatal nystagmus.

A critical perusal of the monograph has not revealed any material omission; it is a model of what such contributions should be, being well illustrated and well documented.

LES ABSCÈS DU POUMON.

By MICHEL LEON-KINDBERG. Paris: Masson et Cie. 1928. Pp. 134. Fr.14.

THIS is one of a series of short volumes dealing with special medical and surgical conditions. The book contains much useful information and it is up to date, although its scope does not allow more than the merest reference to many important matters. The first 94 pages deal with the causation, physical signs, symptoms, diagnosis, and the various types of abscess, and only 30 are devoted to treatment, of which one is given to artificial pneumothorax and less than a page to thoracoplasty. The bibliography extends over ten pages and will be found very useful by those who wish to make a more exhaustive study of the subject. The diagrams are clearly drawn and helpful. There is no index.

BACTERIOLOGY.

A Text-book of Micro-organisms. First edition. By FRED WILBUR TANNER, Professor of Bacteriology and Head of the Department, University of Illinois. New York: John Wiley and Sons, Inc. 1928. Pp. 548. 22*s.* 6*d.*

THIS is an original and courageous book upon bacteriology. Its author has had the vision to discard the trammels of tradition and to write on bacteriology without any systematic description of species, or any account of methods of staining or the preparation of media; one looks in vain for such words as "Agar" and "Gram" in the index, and their absence increases one's interest in examining the book. It is indeed a welcome change from the stereotyped variety of the text-book, and whilst it is quite unsuited to the medical student, may be read with profit by those seeking higher or special qualifications in which a [illegible] knowledge of bacteriology is essential. The medical aspects of the science are scantily dealt with as incidentals, and the main theme upon which the book is constructed is the general biology of micro-organisms with a certain bias towards commercial application. It is written in a jerky, condensed, and didactic fashion, and is consequently not easy to read, but it is a notable contribution for which most teachers of bacteriology will be grateful to the author.

REGIONAL ANÆSTHESIA.

By GASTON LABAT, M.D. Second edition. London and Philadelphia: W. B. Saunders Company, Ltd., 1928. Pp. 1065. 15s.

THIS second edition of a well-known treatise has been extensively revised and somewhat enlarged. It remains one of the best works on the subject in the English language. The author has the gift of clear exposition and is an ardent exponent of local anæsthesia, yet his enthusiasm is tempered by the judgment of experience. The general discussion on the use of regional anæsthesia in Chapter XIV. is especially valuable. Dr. Labat's views of the scope of regional methods coincide with those of most workers, with the notable exception that he seems still to retain a place for paravertebral anæsthesia in abdominal work. Local anæsthetic methods, valuable as they are, must always depend on the selection of suitable patients. A recognition of this fact seems to have crept into this edition, enhancing greatly the value of the author's recommendations. There are many new pictures of great beauty and clearness. Changes are particularly noticeable in the sections on the head, neck, and limbs. There is also a much amplified section on subarachnoid anæsthesia, which has recently appeared in the same form in the new Nelson "Loose Leaf Surgery."

Every surgeon should read this book even though he does not practise the methods of local anæsthesia.

JOURNALS.

JOURNAL OF PATHOLOGY AND BACTERIOLOGY. Vol. XXXII. Pp. 173–348 April, 1929.—The number is dedicated to Sir Frederick Andrewes (of whom an excellent portrait is presented) in celebration of his seventieth birthday on March 31st, 1929.—Further observations on the oxidation by bacteria of compounds of the paraphenylene diamine series, by S. Ellingworth, J. W. McLeod, and J. Gordon (Leeds). Further data on the production of coloured compounds by bacteria by oxidation of paradiamines, some of which are useful in isolation and identification.—Tumour immunity: natural cytotoxins (heterotoxins): protection of cells against homologous antibodies, by T. Lumsden and A. C. Kohn-Speyer (London). The fresh serum of normal animals contains non-specific cytotoxins which destroy the normal tissue cells and the tumour cells of other species. The tissue cells and tumour cells of an animal are protected against damage by homologous cytotoxins, whether pre-existent or experimentally produced.—Immune reactions and cancer, by F. C. Pybus and H. R. Whitehead (Newcastle). No evidence could be obtained of the existence of antibodies common to malignant cells from different animal species.—The effect of certain factors upon the growth of the pneumococcus, by H. D. Wright (London). For full growth the pneumococcus requires nitrogenous substances (which are adequately supplied by ordinary peptone), some fermentable carbohydrate, and some unknown relatively thermolabile substances which are abundant in blood and yeast, and occur in smaller amounts in meat extract, serum, and peptone.—The effect of growing smooth and rough cultures in serum, by J. A. Arkwright and R. M. Pitt (London). Culture media containing serum with somatic agglutinins for a smooth strain of the typhoid bacillus have a strong tendency to convert a smooth culture into the rough form in one or two weeks.—The fate of colloidal iron administered intravenously, by C. J. Polsen (Manchester). The excess of iron is stored mainly in the liver.—The rôle of the reticulo-endothelial system in [illegible]llosis, by S. B. Rybinsky (Kier). Intravital [illegible] with trypan blue of artificially infected mice [illegible] histiocytes accumulate about the worms especially at the poles of the capsule.—Antivaccinial serum, by C. H. Andrewes (London). Generalisation from intradermal or intravenous inoculation can be prevented by an adequate dose of immune serum. Serum which reaches the tissues five minutes before the virus is far more effective than when the virus is five minutes ahead of the serum.—The Schick reaction and circulating antitoxin, by A. T. Glenny and Hilda Waddington (London). Guinea-pigs are Schick-negative if their serum contains at least 1/250" unit of antitoxin per c.cm.—The importance of thermolabile streptococcal toxin with special reference to its cytolytic effect on leucocytes, by H. A. Channon and J. W. McLeod (Leeds). Hæmolytic streptococci, in addition to the well-known very thermostable Dick toxin, produce a thermolabile toxin with a vigorous leucocytolytic action which is probably of more importance than has been supposed.—Two cases of myelomatosis: (1) diffuse plasma celled, (2) with tumour-like masses and visceral lesions, by D. F. Cappell (Glasgow).—An improved medium for the isolation of *C. diphtheriæ:* trypsinised serum tellurite copper sulphate agar, by V. D. Allison and T. H. Ayling (London). Copper sulphate inhibits spreading *proteus* organisms which may be very inconvenient.—Hydatid infestation (*Echinococcus granulosus*) in sheep, oxen, and pigs, with special reference to daughter cyst formation, by N. H. Fairley and R. J. Wright-Smith (Melbourne). *Echinococcus granulosus* is the new name for *Tænia echinococcus*. The authors give a very thorough study of the occurrence and anatomy of its hydatid phase in sheep, pigs, and oxen, and discuss fully the formation of the daughter cysts. They refute the theory that daughter cysts may arise within the cuticle.—A case of malignant hæmangeiomatous endothelioma, by J. Gray (Aberdeen).—A new design of microscope lamp, by C. E. Jenkins (Salford).—The incidence of primary carcinoma of the liver in South India, by P. N. Basu and A. Vasudevan (Madras). The condition is much more frequent than in Western Europe.

Reports and Analytical Records.

ROTHMAN'S RHODESIAN CIGARETTES.

(ROTHMAN'S LTD., 5 AND 5A, PALL MALL, LONDON, S.W.1.)

THESE cigarettes are made of Rhodesian Virginian tobacco. Each cigarette weighed 1·22 g.; approximately 23 cigarettes weigh 1 oz. The paper of each cigarette weighed 0·047 g. On analysis the following results were obtained:—

Moisture	11·50 per cent.
Ash	8·66 „ „
Sand	0·42 „ „
Nicotine	1·00 „ „
Oil	1·60 „ „

These cigarettes are well made, of even texture, and do not irritate the throat when smoked. The low percentage of ash and sand shows that the tobacco is carefully selected and of the Virginian type. The nicotine is distinctly low as also is the oil.

FLORANGE.

(CLEEVES, LTD., CLEEVEDALE PARK, LONDON, S.W.4.)

"Florange" is a fruit syrup with a most refreshing, agreeable, and pleasant flavour of oranges. For use one part is mixed with 4 to 5 parts of water or soda-water. On analysing the syrup the following results were obtained:—

Sugar..	65·9 per cent.
Water	31·2 „ „
Acid (as citric acid) ..	2·18 „ „
Ash	0·05 „ „
Non-sugar extractives, fruit fibre, essential oil, &c. ..	0·67 „ „

These figures show that "Florange" is made of materials of high quality. No preservatives were detected.

E LANCET.

SATURDAY, APRIL 27, 1929.

KING'S CONVALESCENCE.

's message of thanks to his people has
y the welcome news that his convales-
assured, and that no further daily
to his progress will be issued. The
sion has followed with anxious interest
the story of his long illness which began
o, the first formal bulletin being issued
und will join with a special pride in the
of thankfulness that the measures
he KING's treatment have ended so

FECTIVE USE OF RADIUM.

m Subcommittee, whose report we
st week, stated that the amount of
le *to-day, although greater than it was*
ite inadequate even to cope with the
needs of medical treatment. While
thods have been elaborated for the
ancer by radium in almost every region
ne radium required for the purpose is not
ommon policy exists among the hospitals
Sution or use. The Committee recognises
y years to come research and treatment
e to be intimately associated if progress
de, for our present knowledge is not
to decide whether the gamma radiation,
essential part of radium therapy, is best
se quarters to malignant growths within
whether the future lies rather with
es of penetrating rays applied at a
may be recalled that the first medical
radium therapy were the dermatologists,
radium to the surface of more or less
rowths. The next advance was made by
pathologists, DOMINICI and REGAUD, who
wths by actually inserting the radium.
work began great advances have been
gical radium therapy, and in this country
leveloped on the side of surgical technique
ses it must be said most ingeniously) to
tive neglect of the possibilities of treating
ternal radiation with a large quantity of
viously, there can never be such a thing
y of irradiation of a tumour by the
asertion of tubes, needles, seeds, or any
ources of radiation. Take, for instance,
he usual methods for treating inoperable
the neck of the uterus; the insertion of
Ae cervical canal, along with applicators
o supplement their action, inevitably
regions of possibly invaded tissues
irradiated. A malignant growth of the
hich the glands are already involved
distribution of malignant cells which
geometer to irradiate uniformly by
bes. The problem is still more difficult
f a tumour of the breast with all its
ications. This has not discouraged so
worker as G. L. KEYNES, and his *results are certainly not to be despised.* But when the numerous tracks of growth in such cases are visualised, does it not seem rather much to expect that any implanting of radium tubes can cope satisfactorily with advanced disease?

For these reasons the method of applying gamma rays externally deserves the most careful consideration by those who are to put into effect the recommendations of the Radium Committee's report. In the view of a correspondent (see p. 898) whose experience carries weight, the logical development of our present-day knowledge is the use of large quantities of radium at a distance from the body. Let us suppose that a deep-seated tumour is exposed to the gamma rays from as much as 4 or 5 grammes of radium element, held at a distance of 10–12 cm. from the surface of the body. If the radium is placed in a suitable container the lateral spread of the rays can be prevented to some extent, and an almost cylindrical beam may be pictured entering the surface of the body and diverging only slightly in its passage through the tissues. A slightly conical zone of radiation extends from the incident to the emergent surface, the intensity gradually gettting weaker owing to increased distance and absorption. The question to be considered is this: can deep-seated tumours be adequately treated in thi way, so that the malignant cells get the necessar dose without the skin suffering any serious damag If the answer is in the affirmative, then the principle of selective action requires no further demonstration and a method exists by which patients can avoid operation. Evidence is accumulating from the clinics of Paris, Brussels, and New York that these expectations are not groundless, but there has not y been time for more than preliminary reports on this work. In this country there is no centre where the method is being tried. Individual gifts of radium a rarely big enough to supply the large amount of radium needed for this type of treatment. We trust that the national scheme outlined by the Radium Committee may lead to the formation of one or two centres where the value of the method can be determined.

◆

PROFESSIONAL HOSPITALS.

WE publish on page 908 a letter above the signature "Forward," which contains the brave notion tha the counter-actions implicit between a State hospita and a voluntary hospital system would disappea under a scheme whereby the medical professior itself would control and manage the institutions a part of the professional machinery—as "their own industry," in the words of the writer. The schem follows on these two assumptions—first, that th arguments against a State service, which have bee from time to time adduced in these columns, hav been found convincing; and, secondly, that the weal places in voluntary hospital administration, a briefly brought forward, are of such a nature tha the medical profession might be well advised graduall to withdraw their support of them. The alternativ is the setting up of a system of hospitals, which fo convenience may be termed "professional hospitals," to be managed by the medical practitioners of eacl area. *At a time when the whole hospital adminis tration of the country may be described as unde public review in the light of recent legislation* "Forward's" communication invites comment.

The first reflection that his proposal evoke is that to a great extent hospitals, whether ir receipt of State subsidy or conducted on the voluntary principle, are at the present moment in respect of their great responsibilities conducted by the medical profession, and recent debates in the House of Lords during the passage of the Local Government Bill have indicated that there is no intention to change this fundamental principle of good management. But further reflection suggests that the proposal underlying our correspondent's letter implies both a yet wider and more intimate connexion between all the practitioners of an area and the hospitals in their immediate neighbourhood, while the erection of further institutions to receive public subsidy is contemplated, not, apparently, so much to meet an admitted shortage throughout the country of bed accommodation as to replace institutions conducted under systems which have been found wanting. It is, of course, out of the question that any immediate move towards the fulfilment of "Forward's" policy should be made, for economy of money, time, and effort alike would forbid such a course, but the scheme is a timely, if exaggerated, reminder of the professional ideals which, more and more, the enlightened public should be, and are becoming, willing to accept. Medical institutions must to-day be so managed that the actual work of general practice is brought into close elation with hospital administration. And this is view which received wide approval when the Interim Report of the Consultative Council on the future position of medical and allied services was published nearly nine years ago.[1] This Report to the Ministry of Health, although made in circumstances which have in many directions altered, ad for its chief message the need for a systematised provision of medical and allied services, to be applicable to a given area, and to be supplied y the medical profession as a whole, the general ctitioner being the first link in a logical chain with the consultant, the specialist, and the medical auxiliary. Thus, in the Report, there will be seen the outline of an organisation which would have much the same general effect as that which is aimed at by "Forward," although time is postulated during which the necessary uniformity and inclusiveness of the proposals may develop. Our correspondent, and the many who we know will be in agreement with his scheme (however previous or revolutionary), must be prepared, we think, to wait while difficulties of detail are overcome, but their views will assist powerfully to bring about the position, desired by all, that the hospitals of each area should become the place in which the organised medical effort of the locality will be concentrated, and from whence its results will be distributed, while the part played by domiciliary medicine will assume its proper and paramount importance.

Reform along the lines emphasised by the Report of the Consultative Council had been projected in tain respects for many years by the British Medical ociation, whose scheme for the establishment of pitals, clinics, and treatment centres for different es has much in common when dealing with institional treatment. The great difference between the professional hospitals" suggested by our correspondent, and the existing institutions, either as they are, or as they may be, lies in the method set out for election to the staffs. "Forward" writes: "Let the country be divided into suitable areas—smaller in towns, larger in the country. The medical practitioners of each area would combine to elect a staff of consulting surgeons, physicians, oculist, aurist, and the rest." The election to the staff is the great problem. The unworkable nature of the proposal thus summarily stated by "Forward" is obvious, and so are the waste and unfairness manifest in any principles which exclude the general practitioner from the staff. Apart from the intensive training of students, he is often the man whose counsel his colleagues would especially value, so that there should be the best opportunities for its supply. These are the large things which "Forward" makes us contemplate in his brief delivery, and the time for their contemplation is now.

◆

SOLAR DERMATITIS.

THE reaction of the skin to the sun's rays is peculiar to the individual. Some tan easily and others not at all. Red-haired persons, or the descendants of such, are prone to develop freckles, and instead of pigmenting are apt to suffer from a transient erythematous dermatitis, followed by desquamation of the exposed parts. Transient dermatitis may ensue on any skin which is exposed without precaution to a bright hot sun when there has been no gradual acclimatisation. These well-known phenomena vary according to the type of complexion inherited; they may be regarded as a specific response of the skin itself and hardly require further elucidation. There is, however, a group of cases in which the response far transcends any degree met with among the non-pigmenting brunettes. It is not a question of colour in these cases. They may be blonde or dark-skinned; in fact the latter seem to predominate, and it is clear that some other factor than a simple skin reaction is responsible for the irritable rashes which follow exposure, and which may be violent even when the pigment protection appears sufficient. The rashes may be urticarial, papular, or vesicular, or mixed, and exceptionally bullæ may form, which heal slowly and often leave scars. HUTCHINSON, who first classified these "summer eruptions," was alive to the fact of their solar causation, but could not, in the light of the science of his day, offer any satisfactory explanation of the dyscrasia. A clue to the underlying factor was first suspected after the introduction of the hypnotic drug sulphonal, when it was noted that some persons with an idiosyncrasy developed hæmatoporphyrinuria and a papular or vesicobullous eruption, sometimes confined to, or at any rate more marked on, the face and backs of the hands, parts which are exposed to light. If albino mice are injected with a solution of sulphonal and kept in the dark they remain well, but if exposed to sunlight for any length of time they quickly die, often with a copious vesicular eruption. Some cases of congenital hæmatoporphyrinuria are also extremely sensitive to light, and it seems fair to assume the presence of some light-sensitising substance in the circulation of the affected persons. The nature of this substance is by no means clear. The large majority of cases examined have no hæmatoporphyrin in the urine, although some contain an excess of indican and other evidence of intestinal putrefaction. Two cases of which we have seen notes improved after a course of Plombières treatment, supporting the view that i some cases the responsible toxin is generated in th bowel and escapes the censorship of the liver possibly gains direct access to the blood strea the thoracic duct. CRANSTON LOW, whose vi allergy and sensitisation command attention, that other substances besides L can act as the sensitising age that they may be derived from cereals, especially wheat.

---

[1] THE LANCET, 1920, i., 1183 et seq.

Our knowledge of the nature of these circulating toxins is much in the same position as in the case of urticaria, in which Sir THOMAS LEWIS has convincingly demonstrated the potency of histamine and histamine-like bodies, injected locally, in producing an eruption clinically indistinguishable from nettle-rash. It is not unlikely that the toxins responsible for urticaria and solar dermatitis may have a close molecular affinity, for a solar rash may be urticarial and nettle-rash may be papular and even vesicular, especially in the child. Present opinion favours the view that there is not one, but a series of protein molecules which possess the faculty of over-sensitising the skin to the normal stimulus of the sun, and until the biochemist succeeds in isolating or elucidating the metabolic origin of these toxins, our therapeutic measures will continue to be empirical. Moreover, responsibility for the reflex has not been fastened on any particular light rays. Last year at the Paris Medical Society[1] VALLERY-RADOT and others showed a sun-sensitive person, who had responded with an urticarial type of eruption for over 20 years. His reaction was strictly proportional to the intensity of the solar exposure; under ordinary conditions an eruption supervened five minutes after exposure, attained its maximum in one minute, and vanished within half an hour. With a carbon-arc (polymétallique) lamp consuming 30 ampères at 50 cm. distance a similar effect was produced in two minutes. A powerful incandescent lamp furnished with a reflector and working at a distance of 40 cm. produced the reaction in nine minutes, but exposure to the mercury-vapour lamp or to infra-red rays was found to be entirely innocuous, and the authors were able to achieve some degree of improvement in the disability by subjecting the patient to progressive doses, first of ultra-violet and later of daylight itself. This experience, if confirmed, would invalidate the view that the ultra-violet rays are more potent than other parts of the spectrum in eliciting an abnormal response. Heat rays seem to play some part in the mechanism of production, and that there may be a group of rays as yet unidentified, between the ultra-violet and red parts of the spectrum, which are more potent in this respect than either.

SMALL-POX: THE FRENCH RESTRICTIONS.

WE published last week some notes upon the present incidence of small-pox at home and abroad, stressing the effect upon the public mind which the possible distribution of nearly 1500 contacts from the *Tuscania* would necessarily have in this country. Details have been given now showing that, in spite of the extraordinarily favourable opportunity offered for the development of a widespread infection in a closed community on shipboard, only some 44 cases (with seven deaths) had occurred as a result of the case originally taken on board in Bombay, a seaman who was disembarked fatally ill from the disease at Marseilles. The whole situation was viewed in France with great apprehension, and, as that country relies for protection against small-pox upon universal compulsory vaccination to which no popular resistance is ever offered, it was logical that the French Government should propose, and in some places should exact, that no passenger from England who was not prepared with evidence of recent vaccination should be admitted to the country. But a conference between the British and French authorities has since been held at which the weakness, as a preventive measure, of the production of vaccination certificates was recognised on both sides, and, after the discussion of four varying proposals, machinery has been evolved under which, while Article 42 of the International Sanitary Convention, 1926, is followed, the British system of surveillance is also to be observed. An announcement from the Southern Railway states that until further notice passengers landing in France and not possessing a vaccination certificate "not less than ten days and not more than five years old" will require to fill up a sanitary passport—a yellow cardboard form to be obtained en route, when they will be kept under observation in France for 14 days if necessary, but passengers merely passing through France will experience no difficulty. Passengers who have been vaccinated within the required period will be given a receipt for their certificate of vaccination and for them no special or "health-passport" will be required. Others will retain part of the yellow form and will have to report themselves to the health office or *mairie* of the locality to which they go, and they will *be unable to leave that locality within 14 days* without notifying the authorities. It will be apparent that such a wide-reaching organisation as this will entail great trouble upon the French administration, for in effect the machinery is set in action against an undifferentiated population which is only employed in Great Britain upon a limited number of persons who have actually been in contact with the disease. But it must be remembered that the attitude of the French, as a properly vaccinated nation, is a perfectly correct one—how correct will be seen from the words of our Paris Correspondent this week. In France reliance is placed upon vaccination to prevent small-pox, and the French statistics prove that their reliance is justified. Their observations indicate that such cases of small-pox as occur are introduced from without, the sources of infection being derived from countries where the regulations for vaccination are less strictly observed. Having this situation in view the first impulse of the French authorities was to ensure that those coming to France should do as France does; but a closer consideration of the circumstances has convinced the French authorities that the compulsory vaccination of all incomers would not compass their objects, and it has now been decided, with infinite trouble to those authorities, that the British system of surveillance should be employed in lieu of compulsory vaccination.

In the meantime it would appear that the measure of the risk run by the British community through the distribution of contacts from the *Tuscania* has been taken. Notifications to local sanitary authorities should ensure the safety of the population, although an occurrence, which we report from Acton, reveals how ignorance may lead individual citizens to withhold from the sanitary authorities the information necessary for the accomplishment of public duties. Of 28 cases reported in England, 7 were from the Metropolis, 6 from Outer London, 7 from the North and 8 from the South; 13 of the Scottish cases occurred in Glasgow, 1 in Aberdeen. The date on which the last London case sickened was April 7th.

DONATIONS AND BEQUESTS.—The third Earl of Durham left £1000 each to the Durham County Hospital and the Gateshead Dispensary.—The first Baron Hollenden left £8000 to charities, including £1000 each to St. Bartholomew's Hospital and St. Mary's Hospital, Plaistow, and £500 to the Seaside Convalescent Home for Children, Birchington, Kent.—Mrs. Eleanor Barrett Palmer, of Mariston House, Newbury, amongst other benefactions, left £500 each to the Helena Nursing Home, Reading; the Hospital for Incurables, Putney; the Royal Berkshire Hospital, and the Children's Cottage Hospital, Cold Ash, Newbury.—Mr. John Henderson, of Glen Tower, Kelvinnore, Glasgow, left £1000 each to the Western Infirmary, Glasgow, and the Royal Infirmary, Glasgow; and £500 each to the Victoria Infirmary, Glasgow, and the Royal Hospital for Sick Children, Glasgow.

Annotations.

"Ne quid nimis."

RAIN AS A SOURCE OF POTABLE WATER.

To most town-dwellers the idea of drinking-water from a rain-tank seems to belong to a past age, but country practitioners know well that many districts still find the cost of a piped supply prohibitive. Mr. Thiselton-Dyer has recently reported to the Ministry of Health [1] on an investigation he has made in three rural areas where rain-water is still in use for all domestic purposes. The usual method of storage is a circular underground tank built of brick and cement and fitted with a hinged wooden cover or stone slab with a cast-iron lid. In some districts the water is taken out by means of a pump in the scullery, but in most the only method is a bucket dipped into the tank. The size of the tank varies, but the usual aim is storage for two months' supply on a basis of ten gallons per head per day. In one area the local authority insists on a minimum 500-gallon tank. The new houses that are being built for town people, who know the delights of country life without its difficulties, have smaller tanks than those supplied in old cottages for folk who know all about the difficulties of dependence on rain-water. On the whole there seems no danger of drought, for the dry summer of 1921 has left no tales of graver shortage in these districts than was experienced where people depended on springs or rivers. With an average rainfall more rain seems to fall on the roofs than can be stored in the tanks, and the difficulty that has to be met is the expense of providing bigger tanks. Large supplies could be obtained from the roofs of churches and public buildings, but the expense of fitting them with good gutters and leading the water to large tanks would have to fall on the local authority. The state of existing gutters in cottages and bungalows varies considerably. Some of the tanks are simply fed direct from the neighbouring gutters, others are fed by stoneware pipes from all the gutters of the house. Sometimes there are no arrangements for cleaning the roofs or filtering the water; an old stocking may be tied round the pipe to serve as filter; sometimes domestic filters are used. Such a supply in a dusty village with factories might prove unsatisfactory, but in open country or hamlets the unfiltered roof water seems to give little trouble. In fact, in the districts inspected, there was no evidence of any ill-health from the rain-water supply, although in many cases the underground tank was at a lower level than the cess-pit and leaky cess-pits were observed. Since it has been found essential for the preservation of local amenities that each house should store its own water and not share a tank with neighbours, the water-supply of any household is only in danger of contamination by the excreta of members of that household. It is an interesting speculation whether this gives rise to a familial immunity which lasts until it is upset by the coming of visitors. Some people boil their drinking-water, but this practice is by no means universal. The tanks are cleaned out when they get nearly empty—which may happen once in two years—but not otherwise, as the people fear lest a period of drought catch them with emptied tanks. When the water becomes smelly a small lump of lime is thrown in to " clear " it. Nevertheless the water in most of these tanks looked clean, and there seemed to be no mud at the bottom.

It seems clear, as Mr. Thiselton-Dyer says, that " provided people are accustomed to a limited supply of water there is no reason why rain-water should not be looked upon as a direct source of supply where the cost of a piped supply is prohibitive." The problem is an immediate one, and not merely that of a number of old cottages, for over 30 districts are dependent on this water-supply, and the new houses and bungalows that are being built are constructed on the same system, except that the water is universally collected in iron gutters and led down iron pipes; slate and asbestos cement sheets replace the older tiles, and the tanks in the new buildings are protected from pollution. The kind of house that is being erected at the present time is a bungalow for four with a roof area of 575 sq. ft. and a tank of 1000 gallons capacity, thus providing—at the rate of five gallons per head—for a drought of the traditional 40 days. The Ministry's report points out that rainwater-supply requires supervision and control just as well-water does, and that local authorities ought to be authorised to make the necessary by-laws governing the capacity of the tank and its situation and construction. The size must obviously vary with the rainfall, the presence of secondary sources of supply and the uses to which the water is to be put—occasionally water-closets and even baths are supplied by a rain tank—but the by-laws must ensure adequate distance from any dung-heap, privy, or cesspool, according to the nature of the soil, and should provide that the tank be of slate, stone, cement-concrete, brick and cement, or metal. Wooden barrels are undesirable. If the tank is underground it should be lined with impervious material and should project six inches above the surrounding soil to avoid surface drainage. The supply tap should be three inches above the bottom to avoid drawing off sediment, which, moreover, is apt to be disturbed by a pumping apparatus. At a lower level there should be a drain cock unless the tank is underground, and the tank should be cleaned out annually. By-laws should also require proper provision for ventilation and removal of overflow, and should cover the institution of public supplies from such sources as the roofs of churches and other public buildings.

There are some other practical considerations that arise from the use of rain as a source of potable water. In smoky districts rain-water often has an unpleasant taste which it is extremely difficult entirely to remove, although filtration through charcoal or activated carbon may mitigate the drawback. Speaking generally, the use of rain-water is to be encouraged from the epidemiological point of view. If storage is watertight pollution from human sources becomes impossible, and although the excreta of birds and lower animals may be objectionable, the danger of disease being transmitted by them would seem to be remote. The rat, however, which is a sort of reservoir of leptospiral organisms, has an uncanny facility for reaching all sorts of apparently inaccessible places, and in a few instances typhoid bacilli have been isolated from the excreta of gulls. Should it be considered desirable to sterilise rain-water, this can readily be done by means of chlorine, permanganate, or excess lime. If heat is used it is sufficient to bring three parts of the water just to the boil and to add a fourth part when in five minutes the water will be safe to drink.

PLAGUE PROBLEMS IN NORTHERN ASIA.

THE reports of the North Manchurian Plague Prevention Service are always eagerly awaited for the new light they throw on the ætiology of this disease. During the period covered by the sixth report, which is now before us, there were no severe epidemics of plague and no far-reaching investigations could be undertaken. In the summer of 1928, however, outbreaks of bubonic plague occurred in Outer Mongolia, Shensi, Shansi, and in Fengtien Provinces, resulting in 500 deaths, but the accounts of these outbreaks are not yet complete. Two communications in the present volume are from the distinguished pen of Dr. Wu Lien Teh, who edits the reports. He has reached the conclusion that the fleas of the tarbagan, as well as those of the susliks, or marmots, play an important part in spreading plague in winter as well as in summer. The period of hibernation passed by some of the wild rodents suffering from plague is not, as has sometimes been assumed, a hindrance to the perpetuation of the disease, but is an indispensable link in the preservation of the virus. In the case of the tarbagan some of the animals show signs of recovery from the infection; more frequent probably under natural than under laboratory conditions. Dr. Teh believes that the pneumonic form of plague is dependent upon epizoötics and human cases of bubonic plague. Whatever is done for the eradication of these will eventually help to stamp out the pneumonic form. An article on the international aspect of the problem is worth perusal, as well as the descriptions of the ectoparasites and the amœbæ of the tarbagan, the habits and nesting burrows of Transbaikal rodents, and a discussion of the problems of cholera and scarlet fever in China and Japan.

NORDISK MEDISINSK TIDSSKRIFT.

THE birth of a new medical journal is apt to provoke that sentiment to which Abernethy is said to have given voice on facing a large new class of medical students. But there is no need for pessimistic forecasts in the case of *Nordisk Medisinsk Tidsskrift*, as it has a very definite place to fill, and its sponsors are both numerous and influential. Already there are two classes of medical journal in the Scandinavian countries—the strictly national journals, published respectively in Danish, Finnish, Norwegian, and Swedish, and the inter-Scandinavian series of "Acta" published in English, French, and German. Now the new journal, a weekly, is inter-Scandinavian also, but it is published in one or other of the Scandinavian languages (all good Scandinavians read each others' languages), and so, at the cost of not being very intelligible to extra-Scandinavians, it has retained its Scandinavian character in word as well as in thought. The first two numbers follow conventional lines, a certain number of original articles being followed by short abstracts of other Scandinavian journals. The format is pleasing, and the technical work shows evidence of the professional hand. The regional editors are E. Meulengracht (Copenhagen), B. Runeberg (Helsingfors), R. Gording (Oslo), and G. Holmgren (Stockholm), while the editorial committee includes V. Bie, N. Rh. Blegvad, E. Warburg (Copenhagen), G. Becker, S. A. Brofeldt, F. Langenskiold (Helsingfors), O. Hanssen, O. Scheel, A. Tanberg (Oslo), H. Bergstrand, A. Lichtenstein, G. Liljestrand (Stockholm). Special subjects each have their own sectional editor, the names of whom appear on the title-page of the issue. The editorial offices of the journal are at Eriksbergsgatan 1 A, Stockholm.

THE RAY TREATMENT OF ANGINA PECTORIS.

THE treatment of angina pectoris has always constituted a difficult problem. No satisfactory medical procedure exists, and the operative therapy is uncertain and dangerous. One application of ray treatment is that introduced by Prof. A. Henriques, of Tulane University, who claims[1] to have relieved high blood pressure, with its attendant anginal attacks, by gamma rays from 50 mg. of radium applied for an hour to each side of the skull at a point just in front of and a little above the external auditory meatus. In France a number of communications[2] on the X ray treatment of angina pectoris have been made to the Société Médicale des Hôpitaux. An account of some of these is given by the editors of *L'Année Médicale Pratique*, in this year's edition of that valuable reference book.[3] The volume contains two articles by Dr. C. Lian and Dr. R. Barrieu, one dealing with results and the other with indications and technique, constructed from a large number of papers. Dr. Lian is also the editor of the year book. The authors' pathological investigations showed that angina pectoris is a wide syndrome, including all the paroxysmal conditions in the precordial region which are accompanied by thoracic constriction and pain radiating into the left arm. They term it "the cry of distress of the cardiac plexus." The sedative action of X rays on other peripheral and visceral syndromes encouraged their trial in angina; and after some initial reverses the authors claim to have evolved a method successful in 87 per cent. of cases. The relative insensitivity of muscle tissue to X rays prevents the treatment from having a bad effect on the heart; as they remark, the heavy doses given for cancer of the left breast do not cause cardiac injury. Nevertheless, the treatment should not be undertaken in the aged, in those with severe incompetence, or during crises, but diathermy may be applied in the attack. The authors prefer radiations of moderate penetrating power and minimal doses spread over a large number of treatment. Dr. A. Nemours's technique employs a 25 cm. spark, a filter of 5 to 6 millimetres of aluminium, a current of 2 milliampères, and a focal-skin distance of 30 cm. Applications may be made either from in front or behind. The anterior field is divided into two parts, the upper measuring 10 cm. by 10 cm. and situated over the second intercostal space, and the lower situated just beneath and a little to the outside. The posterior fields, of the same dimensions, are respectively above the spine of the shoulder-blade and below it. Irradiation is carried out for 20 minutes at a time, three times a week, only one field being treated at each session. The whole treatment takes from four to six weeks. A variation is that used by Dr. Marchal, who administers progressive doses. His factors are the same as those of Dr. Nemours, except that his tube current is 2·5 milliampères instead of 2; he irradiates a field 20 cm. in diameter situated over the inside of the third left intercostal space, and one of the same dimensions over the third dorsal vertebra. During the first week the patient receives three treatments of five minutes and about 200 Rontgen units each, two in front and one (the second application) behind. In the second week the time is extended to ten minutes, and so on, increasing at the rate of five minutes a week, until the end of the fourth week. A fifth week is given in particularly refractory cases. The authors consider that the progressive doses are preferable, as they attain the same results as the fixed dose with a smaller amount of energy. We look forward to the publication by English radiologists of their results with this form of treatment.

PREVENTION OF JUVENILE RHEUMATISM.

THE interest which has been aroused of recent years in the menace of rheumatism in childhood, and which was brought to a focus at the Bath conference last year, shows no sign of abating. On all sides there is evidence that physicians, hospital and school officers, and public health authorities are casting round for means by which the information collected at this conference may be applied to the prevention of rheumatism and its attendant evils. Dr. T. W. Hill, assistant medical officer of health of Willesden, has been at pains to set out[1] what he regards as the essential steps in prophylaxis, and he makes some suggestions which, even if they may be in some respects Utopian, can yet be of service in pointing towards an ideal. He emphasises the fact that the earliest premonitory symptoms of rheumatism frequently occur in the pre-school, not the school, age. If these children are to come under observation the provision of some kind of inspection in nursery schools is necessary. He regards as an essential preliminary to any effective campaign the registration of all "pre-rheumatic" children—i.e., children "of rheumatic heredity, direct or remote." He does not, however, attempt an estimate of the approximate number which this survey would include; it seems not unlikely that, according to the somewhat nebulous criteria at our disposal, this category would comprise a considerable proportion of the child population. Dr. Hill recognises the housing question as the main factor in causation which can be attacked at present. He puts forward a number of suggestions for the elimination of damp, and refers hopefully to the experiments in glass and concrete construction which have been described in America. On the vexed question of tonsillectomy he is in substantial agreement with the majority of recent writers. He is emphatic in condemning indiscriminate removal, and would await the infection of tonsillar glands or the occurrence of repeated sore-throat. In children who already show signs of rheumatism the results which he observed did not inspire optimism. He concludes that the only hope of success lies in early operation, but even this did not always avert cardiac disease in the cases which he observed.

INDUSTRIAL CONDITIONS OF THE DEAF AND DUMB.

AT the request of the British Deaf and Dumb Association the National Institute for the Deaf has inquired into the industrial conditions of the deaf and dumb and has issued a report.[1] It is estimated that there are some 40,000 persons in the United Kingdom who were either born deaf or became so sufficiently early in life to prevent the natural development of speech. This is about 1 per 1000 of the population, a number surprisingly big for an estimate which does not include those who become more or less completely deaf in youth or adult life—that is, the "deafened" and the "hard of hearing." Of this large total it is doubtful if even half are known to the 50 special welfare organisations which exist in this country for the care of the deaf, and in many large districts no provision of any kind exists for the welfare of these unfortunates. It will be recalled that the education of deaf and dumb children came under the care of the Board of Education in 1894, and their educational status was greatly advanced when the Education Act of 1921 made it obligatory on education authorities to provide for the special education of every deaf child. Yet according to the Board's statistics, only 4151 deaf children attended special schools in England during 1927. The Institute regards the special school as of first necessity since the instruction there provided creates a distinctive medium of impression and expression in lieu of the naturally acquired and ready speech of normal children. This process is necessarily slow, and although children do not leave until they are 16 they are still seriously behind the normal standard in acquired knowledge and the ability to express it. Even with the power of lip-reading and artificially acquired speech the deaf child is never on the same plane in ready understanding and the use of language as the child who hears, although investigations have shown that on the whole deaf children are no less intelligent even if more sensitive and retiring than their fellows. From the economic standpoint it is clear that the deaf are potentially the most remunerative of all the physically defective classes, provided they are given a fair chance. But being compelled by their infirmity to remain in special schools until 16 years of age, they have less chances of competing with adolescents who have already gained two years' experience in their several crafts. Both the health and unemployment insurance schemes demand payment for employees at 16 years of age, thus further weighting the scales against the deaf. The various liability and compensation Acts are sometimes cited by employers as reasons for refusing to engage deaf workers in view of a prevalent (but unverified) fear that the deaf are more liable to accidents than those who can hear. Apart, however, from trades involving dangerous machinery, experience suggests that the deaf employee with his quickness of eye and sensitiveness to danger is as immune from accidents as one with normal hearing. The present position is that in those areas from which statistics could be obtained some 40 per cent. of the male and 47 per cent. of the female deaf are only casually employed, if at all. In other localities the position is no doubt worse. It is computed by the Institute that 20 per cent. of the deaf are of high and 60 per cent. of average intelligence; with suitable training and help in finding jobs all of these should be capable of skilled employment. Between 15 and 18 per cent. will only be fit for unskilled jobs, and the small remainder with definite mental defect will be unemployable. Since the difficulties are partly a question of legislation and partly of employment in special trades and crafts, it would require an official inquiry for their solution. Prevention is outside the scope of the Institute's report, but it is now generally agreed that many acquired types of deafness can be obviated, in part or in whole, by early detection and attention. It is on the earliest years of life that the light of preventive and therapeutic measures should be focused.

ARRESTED RESPIRATION IN INFANTS.

SOME years ago Dr. G. F. Still described in our columns[1] five cases of what he termed attacks of arrested respiration in the newly-born and suggested that these attacks were probably due to some affection of the respiratory centre. A. Peiper[2] has lately given a full and interesting account of this curious condition, linking up his observations with work on the situation and nature of the respiratory centre in man. At the beginning of his paper he quotes experiments on the respiratory centre in animals, especially those of T. Lumsden in cats. This worker described four centres situated in the pons and medulla. In the upper part of the pons there is a "pneumotaxic centre" which exerts periodic inhibition on the next lowest centre termed the "apneustic centre." This centre, if cut off from all influences coming from above, causes prolonged inspiratory tonus or holding of breath. Experimental lesions at a lower level, approximately in the middle of the medulla, cut off the influence of the apneustic centre and the experimental animal can now only inspire by gasps, though expiration is still properly performed. Lesions just below this level cut off the power of expiration and leave only gasping, so that the lowest centre is known as the gasping centre. These results have some importance if they can be confirmed in the human subject, and it is only by observing respiratory disorders and their pathological basis that this may be done. Having this end in view Peiper has studied several examples of respiratory failure in infants, recording the respiratory movements upon smoked drums. The attacks of sudden cessation of breathing which he has investigated occur during the first few days of life and especially in infants premature and under weight. The first attack may be sudden and without warning, and very often comes on during feeding. Breathing suddenly stops, the colour becomes blue, the heart sounds are distant, the muscles relax, reflexes are abolished, and the child lies in a narcotic state. Death may supervene in the first attack, but more usually, just as death seems imminent, the mouth is opened, there is a gasp, and respiration is re-established; the normal colour and action of the heart quickly return and reflexes can be obtained again. These attacks may be repeated and not infrequently the child succumbs in one of them. (In Still's series there were four deaths in five cases.) Peiper thinks that the lesion is in the respiratory centres, though the exact pathology remains obscure. Treatment, he says, must aim at stimulating these centres and keeping the heart going during the attacks. The child should be watched literally day and night, so that artificial respiration can be started the moment an attack begins. Pure oxygen is a less valuable stimulant than oxygen to which 5 per cent. carbon dioxide has been added for its effect on the centres. Lobeline is said to be useful, and an intramuscular injection of 0·003 g. as a single dose is advocated. Adrenalin may be injected direct into the heart as a last resort if the child seems to be on the verge of death.

[1] THE LANCET, 1923, i., 431.

[2] Jahrb. f. Kinderheilk., March, 1929, p. 129.

Such studies as these may help to elucidate some of the physiological and pathological aspects of respiration. Besides throwing light on arrested respiration in infants they have a bearing on the so-called asphyxia neonatorum.

CLOSED PNEUMOLYSIS.

In many cases of pulmonary tuberculosis, including most of those occurring in early adult life, artificial pneumothorax is the only method of treatment that offers any prospect of cure. The success of such treatment depends chiefly upon obtaining effective collapse of the diseased lung. If the collapse is incomplete ultimate spread of infection to the opposite lung is almost inevitable. In a recent article Dr. R. C. Matson[1] says that the success of artificial pneumothorax treatment is "almost in direct proportion to the number and character of adhesions present" and attributes 40 per cent. of its failures to this cause. The attempt to stretch adhesions by increasing the intrathoracic pressure is seldom satisfactory, and is not without danger. Grave risks are also incurred when open operation is performed. Less danger and a greater measure of success have attended the cauterisation of adhesions by the method of closed pneumolysis devised by Jacobaeus, whose thoracoscope permits a clear view of the offending bands and thus enables their severence to be effected with the galvano-cautery. Risk of hæmorrhage and of the liberation of tuberculous infection is stated to be lessened if an endotherm is used instead of the cautery. Before deciding to operate Matson rightly insists that there should be reasonable assurance that the patient will recover if a satisfactory collapse is established. The rules which guide the physician in deciding to induce a pneumothorax will obviously determine his decision whether to persist in his efforts to establish a complete collapse. Matson gives three chief indications for cauterisation: (1) incomplete collapse due to adhesions; (2) satisfactory collapse maintained only by high intrapleural pressures which involve discomfort to the patient and risk of rupture of the lung; (3) when in a previously satisfactory pneumothorax the organisation of bands, or adhesions, is causing expansion of the collapsed lung. The benefit that may be expected from intrapleural pneumolysis in the hands of an expert is shown by Matson's own records, for he was able to convert a partial into a complete pulmonary collapse with the abolishment of cough and expectoration in 63 cases out of a series of 100. It is perhaps needless to add that this method of treatment should only be employed by those whose experience of collapse therapy is extensive, and who by constant practice have mastered the necessary technique. The correct use of the thoracoscope and the manipulation of the endotherm or cautery demand the highest degree of skill.

ANTITOXIC SERUM IN SCARLET FEVER.

There is no longer any doubt that certain strains of streptococci produce a true toxin, in addition to a destructive substance, "hæmolysin," which does not seem to fall into that category. Such streptococci are chiefly associated with scarlet fever; and two strains, known to bacteriologists as "Dick" and "Dochez," are recognised as being true toxin-forming strains. The toxin produced by streptococci is not comparable with that of diphtheria, save in that an antitoxin is procurable, for it is not the chief weapon of the organism. It is of slight virulence to laboratory animals, though when concentrated, as by the methods of Percival Hartley and R. J. V. Pulvertaft, it is lethal to rabbits. Where, as apparently in scarlet fever, the toxic action of the organism predominates in the clinical picture, the use of antitoxin is followed by excellent results. But the invasive action of the organism is not dependent on the toxin-production.

Many problems remain. In the first place, are all streptococcal toxins, even in scarlet fever, the same? The famous Park strain of diphtheria bacillus is known to be the best toxin-producer, and to yield a high antitoxin of general utility. There is doubt whether a similar strain can be found among streptococci. Wadsworth, Kirkbride, and Hendry[1] bring forward evidence to show that, in fact, the best antitoxins are provided by the Dochez strain—which is fortunate for dwellers in England, where this strain is used to make antitoxin. They further throw doubts on the keeping qualities of the antiserum, which needs careful control. The most urgent necessity, however, is for an adequate method of standardising antitoxin. The accepted one, in America, is the neutralisation of skin test doses in susceptible men. M. B. Kirkbride and M. W. Wheeler have substituted a similar test on goats. In this country the protection of rabbits against death, within a specified time, from intravenous injection of living organisms has been used, with excellent results, by C. C. Okell and H. J. Parish. More recently Hartley and Pulvertaft have suggested the use of concentrated toxin on rabbits; Hartley's method is highly commended in the latest annual report of the Medical Research Council. Wadsworth finds by the skin test method a great variation in the value of antitoxin. Some have as many as 600 units per c.cm.; others are utterly useless, having no demonstrable antitoxin. So long as human beings are necessary for the purpose of standardisation, the antitoxin is of necessity limited in amount, expensive, and, it must be said, unreliable.

There is sufficient proof of the efficacy of this antitoxin, when really standardised, to make it urgent that the problem should be further examined. The introduction of animal tests may put this work on a new footing.

THE GASTRIC DIGESTION OF MEAT.

Some important observations on digestion have lately been made by M. E. Rehfuss and G. H. Marcil,[2] who have compared the results obtained by a fractional test-meal of the usual carbohydrate type and one composed of 60 g. of scraped meat, the two meals being given within 48 hours of each other. After the meat meal they found that the acid response in the normal was 30 per cent. higher and two types of response were noticed, one prompt and decided and the other slow and indifferent. Meat is a true intragastric stimulant and in health is capable of producing the maximal response from the gastric mucosa. The response in disease is no less interesting. Though, as they point out, only a limited number of cases have been investigated, too few to allow of complete generalisation, three groups may be separated. While in purely functional cases and in those with peptic ulcer the meat produces the extra acid response, there was no response to either carbohydrate or meat meal in pernicious anæmia, gastric carcinoma, delayed resolution in lobar pneumonia, and chronic cholecystitis. The intermediate stage, in which the meat response is present but is less than normal, is furnished by such cases as cardiac or renal disease, blood dyscrasias, and "other conditions commonly encountered in medical ward service." In these cases the power of the stomach to deal with meat is merely lowered and not lost. It is suggested that these variations in the response to a meat and carbohydrate meal may be regarded as a measure of

---

[1] Amer. Jour. Hyg., March, 1929, p. 371.

[2] Jour. Amer. Med. Assoc., March 9th, 1929, p. 763.

[illegible] efficiency and that persons who give a [illegible] response to bread and meat, as shown by the [illegible] test-meal, cannot be regarded as normal.

This work is illuminating and suggests several possibilities. It throws light on those puzzling cases where acidity and acid regurgitation are complained of by patients who on investigation, with a carbohydrate meal, show a subacidity amounting even to achylia. The interpretation of the fractional test-meal is beset with pitfalls. It is usually carried out under conditions anything but pleasant or normal to the patient, who is as a rule nervous; the meal itself is unappetising and often distasteful; it is digested in the prone position or partially reclining, with a foreign body in the stomach causing a certain amount of discomfort and usually producing excessive secretion of mucus. There is often a tendency to place too great faith in results obtained under these abnormal conditions, for while it is true that most of these drawbacks may disappear with several examinations, very few patients will consent to become proficient in this method of investigation in the interests of scientific accuracy. The same objection—namely, examination under abnormal conditions—may be urged against other methods daily employed, but this does not answer the objection; it merely sounds a note of caution against accepting results too literally. To this inherent limitation of the fractional test-meal Rehfuss and Marcil have added another in showing how great is the variation of response to different food stimuli. Their work must make the medical man look again at some of the diets he orders. Are we not often too nervous of ordering good red meat for our patients, and giving in its place some patent or partially digested sloppy pabulum which we cheerfully call a "light diet"? Often it is anything but light to the patient. Would it not sometimes be better to clean the gastric lining membrane, make sure the teeth are adequate and efficient, and then try the effect of, say, a nicely cooked chop, carefully masticated, with a couple of slices of dry bread? In tropical climates raw meat juice is of great value where milk is badly borne by an infant with summer diarrhœa and vomiting. The complete change seems to put the child's stomach on its mettle and it usually responds to the challenge.

Apart from its valuable suggestion of a new test for the efficiency of the gastric mucosa, this paper seems to show that we have not sufficient faith in the adaptability of our stomachs.

ANTIVENEREAL MEASURES IN THE STRAITS SETTLEMENTS AND MALAYA.

MORE than forty years have passed since, after an agitation conducted with relentless fervour by Josephine Butler and her friends, the Contagious Diseases Acts, 1864–69, in this country were repealed. An echo of the controversy surrounding this reversal of policy is to be heard in the arguments set out by a committee[1] appointed by the Secretary of State for the Colonies to examine a Straits Settlements Ordinance (No. 15 of 1927) and a Federated Malay States Enactment (No. 18 of 1927). These provisions are substantially similar, their object being to diminish the spread of venereal disease. The sections to which the attention of the committee has been drawn are those permitting the compulsory medical examination of any individual prostitute when there is reason to suspect her of suffering from venereal disease. After careful consideration of the local situation, as well as the general problem, they advise that these sections of the ordinance and enactment shall be held strictly in reserve, and eventually, when alternative legislation can be passed rendering illegal the keeping of brothels, shall be repealed. This does not imply that the committee do not view with sympathy the dilemma which has led to the attempt to strengthen the hands of the local authorities in enforcing the existing law, but that they hold, in agreement with expert opinion in most countries, that the use of compulsion in any form is likely to destroy the atmosphere of encouragement to make the fullest use of the provisions made for free treatment.

The local position is difficult to understand without some reference to the history of the legislation now in force. When, in 1886, Mrs. Butler and her co-workers had convinced Parliament that the subjection of prostitutes to periodical medical examination was a gross interference with the liberty of the subject, besides being useless as an antivenereal measure, the wave of feeling rose so high as to overflow to the Colonies, as far as legislation was concerned, before public opinion there was educated to the need for a change. In the Straits Settlements the system of compulsory medical examination of prostitutes was thus abruptly brought to an end in 1888, and in 1894 the registration of brothels was discontinued there, and also in the Federated Malay States. Unfortunately the local authorities, though they had to obey directions from the Home Government, were not convinced that the innovation would not lead to an increased incidence in venereal disease, as well as to further exploitation of prostitutes, who are, for the most part, non-Europeans of a low type. Fruitless efforts have more than once been made to induce the Home Government to consent to a re-introduction of registration and periodical medical examination, on the grounds that the incidence of venereal disease was increasing. In 1898 the representations were effective to the extent of securing an amendment to the law in both colonies whereby brothel-keepers were made subject to fine or imprisonment if a prostitute in their houses carries on her trade while suffering from any contagious disease. Unfortunately for the success of this scheme, which has now remained in force for some thirty years, some of the brothel-keepers fined for the offence are known to have recovered the money from the prostitutes concerned. The obvious countermove of imposing terms of imprisonment without the option of a fine proved ineffective, since the keepers realised that proceedings could only be based on medical evidence, which in turn could not be obtained without the consent of the woman; if they could persuade her to refuse examination they were safe from prosecution.

This, briefly, was the situation which, in 1927, led to the framing of new provisions which would prevent such evasion of the law. The committee have evidently given the complex situation the most careful thought, have examined many witnesses, and have come to the considered conclusion that, whatever its purpose, the punishment of a prostitute for not complying with a requirement which is not applied to the community generally is not justifiable, and that even the provision penalising brothel-keepers, which was framed at a time when the present system of treatment of venereal disease had not been developed, is now obsolete. They advocate in its place the extension of the powers of closing brothels already possessed by the authorities, in order to prevent a keeper of a closed brothel from starting another. When the policy of suppressing known brothels, which should be actively pursued, has resulted in their decline, legislation rendering illegal the keeping of a brothel should replace the existing provisions. Meanwhile free facilities for the treatment of venereal disease in men and women should be extended, and to this end financial provision should be made for the employment of highly qualified medical men and women at all clinics and dispensaries, and for a development of the health visitor service. The report deserves study by all concerned with the control of venereal disease. It epitomises knowledge painfully gained in the struggle to combat venereal disease throughout the world.

---

[1] The committee consisted of Lord Balfour of Burleigh (chairman), the Hon. Mrs. Alfred Lyttelton, Dr. F. Barrie Lambert, Mrs. Neville Rolfe, Sir O. E. Warburg, and the Rev. W. C. Roberts, with Mr. G. L. M. Clauson as secretary.

Modern Technique in Treatment.

A Series of Special Articles, contributed by invitation, on the Treatment of Medical and Surgical Conditions.

CCXCII.—THE TREATMENT OF LOW BLOOD PRESSURE.

HYPOTENSION may be said to exist when the systolic blood pressure falls below 110 mm. mercury. A low blood pressure is a symptom of many diverse affections. It does not constitute a whole clinical picture as may be the case with hypertension. In most instances it does not even form the dominant feature of the case, though there are notable exceptions to this. The treatment of low blood pressure, therefore, may merely be incidental to that of the underlying condition, but occasionally it is justifiable and even advisable to direct treatment principally to this one symptom.

Patients with low blood pressure may conveniently be divided into three groups: (1) those requiring no treatment; (2) those in whom treatment is usually unavailing; (3) those in whom it is requisite and usually attended with some success.

Patients requiring no treatment.—Many healthy people have a persistently low blood pressure without untoward symptoms; athletes may, indeed, be found amongst this group. No treatment is required, and if instituted would probably do harm. In patients over fifty, moreover, low pressures are often prophetic of longevity and these patients are regarded as good insurance risks.

Cases where treatment is unavailing.—In this category is included "*status lymphaticus*," where the heart and great blood-vessels are smaller than normal and the arterial pressures correspondingly low. It is evident that little or nothing can be done for such patients except to advise such prophylactic measures as prevent any undue strain on the cardiovascular system. The condition styled by Martinet "hyposphyxie," characterised by general malnutrition, blue extremities, and cardiovascular hypoplasia, does not yield very well to treatment, though general tonic measures—good food, well regulated exercises, and massage—may do something to improve the patient's condition. This applies also to the treatment of those types of neurasthenia which are accompanied by hypotension.

Cases requiring treatment.—These cases fall naturally into two classes, those in which treatment is urgent, such as hæmorrhage and shock, and those in which the hypotension is merely one of several symptoms requiring attention. These may be considered in more detail.

Hæmorrhage and Shock.

The low blood pressure of shock or hæmorrhage is largely due to diminution of circulating fluid, either through capillary stasis or through direct loss of blood. In both cases the amount of blood returning to the heart is notably decreased. The treatment, therefore, consists in replacing this fluid by giving ample liquids by mouth, by use of rectal salines, or best of all by the injection of subcutaneous salines. Several pints of fluid may be absorbed from the loose tissue of the mammary or axillary regions in the course of a few hours.

If the blood pressure falls to 60 mm. death usually occurs and if the readings approach this value, therefore, the more rapid effects obtainable by intravenous administration of fluids are necessary. Salines are of value given in this way, but since shock is partly due to loss of colloids, especially hæmoglobin, solutions of gum acacia may be substituted with advantage. Theoretically the appropriate method of replacing the lost fluid is by blood transfusion, particularly in cases of severe hæmorrhage, where it may be repeated, though in many instances salines or gum acacia seem to be equally beneficial. Serum to a pint of which ♏vii., to ♏viii. of 1/1000 adrenalin have been added is also of value, given intravenously, and is recommended by French authors.

The insufficient cerebral circulation consequent on the fall of blood pressure must be treated by posture; the pelvis should be raised, the head lowered, and the limbs bandaged. The usual precautions in shock regarding warmth and quiet also play an indirect part in restoring the blood pressure to normal.

Anaphylaxis.—In addition to the usual nursing principles applicable to all forms of shock, adrenalin seems to be of considerable value in combating the hypotension in anaphylaxis. It should be given subcutaneously in doses of ♏v. to ♏x. of liq. adrenalin hydrochlor., and as its action is evanescent it may be repeated.

A fall of blood pressure may also occur in *anæsthesia* accompanied by symptoms resembling those of traumatic shock. These symptoms can usually be avoided by careful precautionary measures, the routine examination and careful selection of all patients for anæsthesia, avoidance of undue exposure, maintenance of warmth, and choice of a suitable anæsthetic. Chloroform is more likely to produce a fall of blood pressure than other anæsthetics.

The use of *spinal anæsthesia* is contra-indicated in patients with low blood pressure, but where the pressure falls after its use—a not uncommon event—the patient should be kept in bed with the head downwards during and for two days after the operation. In urgent cases intravenous administration of adrenalin, or in less severe cases, intramuscular pituitrin are of great help. Ephedrine and ephetonin also have their advocates.

When, before operation, the blood pressure is very low, due to shock or hæmorrhage, every effort should be made to restore it to normal figures before commencing any surgical procedures. For this purpose blood transfusion or intravenous salines are most helpful.

Conditions of which hypotension is a less urgent, but still important feature, include certain forms of cardiac disease, acute and chronic infections, and various endocrine disorders. In these it has already been emphasised that the fall of blood pressure is only one symptom in the clinical picture and the treatment must, therefore, be that of the whole syndrome. Occasionally, however, in some of the conditions to be mentioned the hypotension is so marked as to form the most important feature of the case and require special attention.

Hypotension in Cardiac Disease.

Low pressures are not common in cardiac disease, whether valvular or myocardial, except in the terminal stages. A sudden fall of pressure in a patient with *hypertension* usually portends serious heart failure, and the patient should have absolute rest in bed with a light diet at first, and suitable warmth. Digitalis is of value if there are signs of back pressure such as œdema and engorged veins, but will otherwise have little effect. Pituitrin in doses of 0·5 c.cm. twice daily may be given intramuscularly with good effect in some cases, but it must be used with care. Similar treatment is suitable in the terminal hypotension of myocarditis.

In *chronic valvular disease* with decompensation the blood pressure is frequently a little above normal, and with improvement in the patient's condition tends to fall. It is thus inadvisable to attempt to reduce the pressure. If, however, hypotension exists from the beginning together with signs of passive congestion, digitalis and rest in bed may be effective in restoring normal pressure.

With *auricular fibrillation*, although the estimation of blood pressure is difficult owing to the variability in the size of the ventricular beats, the average readings may afford a rough guide as to the variations present. In cases with low pressure, if the ventricular rate is rapid, return to normal figures may be obtained by correct administration of digitalis. This should be given either in the form of the tincture in doses of ♏xx. t.d.s. or as Nativelle's digitaline gr. 1/240 t.d.s.

Bradycardia is often accompanied by hypotension and this is especially marked in cases of Stokes-Adams seizures. For the latter condition adrenalin in doses of ♏v. to ♏x. subcutaneously is of great value; possibly part of its beneficial action is due to its effect in raising the blood pressure.

Hypotension in Acute Infections.

Hypotension is a frequent symptom of pneumonia, typhoid fever, influenza, diphtheria, cholera, and other infections. Its treatment will vary accordingly, but as the low blood pressure is mostly due to a combination of two factors these will require special attention. The two factors are myocardial weakness and vaso-motor paresis; treatment varies according as to which factor predominates. In treating myocardial weakness it is essential that the heart shall have ample time in which to recover from the toxic changes which have occurred. For this purpose a prolonged rest in bed is necessary, preferably with the head low; all active movements on the part of the patient should be strictly limited. This is particularly important in cases of pneumonia and diphtheria. When myocardial involvement is suspected in these cases, the period of rest should be extended to from six weeks to two months after the cessation of pyrexia. It is doubtful if drugs have any beneficial action on the myocardium in most of these cases, but digitalis may be useful. In those acute infections where the condition resembles that of shock, cases with sudden pallor, cyanosis, and collapse, pituitrin may be of considerable help.

The second factor, loss of vaso-motor tone, probably plays a larger part than the myocardial factor and especially accounts for the persistence of hypotension after subsidence of the fever. It can probably be treated best by carefully graduated exercises, for example, the Schott exercises practised at Nauheim, or by well-regulated Swedish drills. Massage forms a very useful adjunct. Amongst drugs, strychnine holds an important place for its stimulant action on the vaso-motor centres. It may be given by mouth in doses of 4 minims of the liq. strychnin. hydrochlor., or on more urgent occasions as hypodermic injections of gr. 1/32 three times a day. Indiscriminate ductless gland therapy is to be deprecated, but careful use of adrenalin, given hypodermically in small doses (♏iii. to ♏v), is of value, or whole gland suprarenal (gr. v.) may be given by mouth. Ephedrine hydrochloride gr. ss. twice or three times a day may also be employed, but it is still on trial.

The diet in cases of low blood pressure should be full and nutritious with an abundance of milk, eggs, and cream. Meat should be allowed in reasonable quantity, but it does not seem advisable to overburden a convalescent patient with large amounts purely on the grounds that it is usually restricted in cases of high blood pressure. Similarly, the use of articles rich in extractives, such as liver, kidney, sweetbreads, or meat extracts, although contraindicated in hypertension, are not on that account to be advocated for hypotension. Alcohol should in general be avoided in view of the fluctuations in blood pressure which it produces, but when hardship is entailed by its complete withdrawal small amounts of whisky may be allowed.

Cholera requires different treatment from the other infections, since the low pressure is due directly to loss of body fluids. Similar hypotension may occur in any severe diarrhœa. The fluid must be replaced by oral, subcutaneous, or intravenous administration of salines according to the urgency of the case.

Hypotension in Chronic Infections.

Low blood pressure occurs very consistently in pulmonary tuberculosis and careful search must be made for signs of this disease in cases with persistently low pressure without obvious cause. Treatment will be that of the lung condition; the hypotension rarely needs special attention.

Another possible cause of persistent hypotension is some focus of infection such as may occur in chronic appendicitis, cholecystitis, in root abscesses of the teeth, low grade infections of the genito-urinary tract, and so forth. Treatment consists in the discovery and eradication of the infected area. This may involve surgical intervention or the use of vaccines.

Hypotension in Endocrine Disorders.

The most definite of these is *Addison's disease.* The treatment of this condition is not very satisfactory, but a combination of whole gland suprarenal given by mouth together with carefully spaced subcutaneous doses of adrenalin may do something to raise the blood pressure and relieve the patient's symptoms.

Some types of *pituitary insufficiency* are associated with low blood pressure, and the rational treatment for these cases is the administration of pituitrin 0·5 c.cm. twice daily, intramuscularly, together with whole gland pituitary by mouth.

One further condition may be mentioned under this heading, for although little is known about its ætiology, certain facts suggest its association with a ductless gland dyscrasis—namely *postural hypotension.* In this complaint the hypotension occurs on changing from the recumbent to the erect posture. Some cases are associated with visceroptosis and for these a good abdominal belt with masasge and exercises are of value. Strychnine is also useful. Recently ephedrine has been praised in this connexion and may be tried in doses of gr. ¼ every three hours for several days.

E. NOBLE CHAMBERLAIN, M.D., M.Sc., M.R.C.P.,
Cardiologist and Assistant Physician, Royal Southern Hospital, Liverpool.

The Services.

ROYAL NAVAL MEDICAL SERVICE.

Surg. Lt.-Comdr. R. E. Rampling to be Surg. Comdr.
H. L. Belcher to be Surg. Lt.
Lt.-Comdr. (Retd.) C. H. Petrie to be Comdr. (Retd.).
Surg. Lt. H. L. Duncan is appointed to the *Virid.*

ROYAL NAVAL VOLUNTEER RESERVE.

Proby. Surg. Lt. T. C. Larkworthy to be Surg. Lt.
Surg. Lt.-Comdr. C. C. Elliott is appointed to the *Repulse.*

ROYAL ARMY MEDICAL CORPS.

Lt.-Col. P. Davidson, having attained the age for compulsory retirement, is placed on retd. pay.

Maj. R. P. Lewis to be Lt.-Col., vice Lt.-Col. P. Davidson.

Maj. J. D. Kidd retires, receiving a gratuity, and is granted the rank of Lt.-Col.

Lt. L. R. H. Keatinge is secd. for duty with the Sudan Def. Force.

TERRITORIAL ARMY.

Maj. T. H. Richmond, having attained the age limit, retires and retains his rank, with permission to wear the prescribed uniform.

Capt. J. O. Thomas to be Maj.

Maj. R. C. Aitchison (Capt. Res. of Off.) resigns his commn. in the T.A.

Lt. D. R. McGregor resigns his commn.

INDIAN MEDICAL SERVICE.

Maj. Mozaffer Din Ahmed Kureishi to be Lt.-Col.

Temp. Capt. Daulat Manghirmal Lala, the relinquishment of whose temp. commn. has been notified, is permitted to retain the rank of Capt.

HOSPITAL ACCOMMODATION AT LIVERPOOL.—At the annual meeting of the Royal Southern Hospital, Liverpool, Mr. Allan Paton, the President, suggested that the voluntary hospitals of the city should be superseded by one large hospital with ample accommodation for all patients, including private patients of the middle and upper classes. Such an institution should be within easy reach of the University and served by small casualty stations and ambulances in appropriate parts of the city.

Special Articles.

MEDICAL WOMEN'S INTERNATIONAL ASSOCIATION.

THE PARIS CONGRESS.

THE second quinquennial congress of this Association, which was founded in 1919, was held in Paris from April 10th to 16th, the meeting-place being appropriately the Institut International de Coopération Intellectuelle (Palais-Royal), lent by the League of Nations. Nearly 300 medical women were present, including representatives from America, Austria, Belgium, Bolivia, Canada, Denmark, France, Germany, Great Britain, Hungary, India, Italy, Japan, Norway, Poland, Spain, Sweden, Switzerland, and Yugoslavia. The business done included the transfer of the office of the Association from London, which has been the headquarters for the past five years, to Paris, since for the next quinquennial period the officers have been elected from among the French medical women. Lady Barrett, Dr. Jane Walker, and Miss Louisa Martindale retired from the offices respectively of president, treasurer, and honorary secretary, and are succeeded by Dr. Thuillier-Landry, Dr. Réguin, and Dr. Montreuil-Straus. The newly elected vice-presidents are Lady Barrett (Great Britain), Dr. Tayler-Jones (United States), Dr. Mathilde Salzmann (Germany), Dr. Carcupino Ferrari (Italy), Dr. Dagny Bang (Norway), and Dr. Nechkovitch-Voutchetitch (Yugoslavia). Apart from the general business and the council meetings, considerable effort had been made to provide interesting matter for discussion at the sessions devoted to the consideration of two problems of especial import to medical women. The first of these concerned

Sex Instruction for Children and Adolescents.

Two members had been chosen to circularise selected medical women in the various countries and to summarise their replies to a questionaire in a form which would readily show what, if any, methods of sex education were being pursued in different lands and would moreover bring to light any new suggestions as to procedure or organisation of instruction. In view of the excellent surveys prepared from information received by Miss L. Martindale and Dr. Montreuil-Straus, the actual discussion, which took place on April 11th, was rather disappointing. Matters of general agreement were that a child's earliest questions as to the transmission of life should be answered without evasion, since in this way he acquired some knowledge before it had any emotional significance for him. Most contributors regarded the mother as the most suitable person to give teaching to very young children, and stressed the importance of providing her with opportunities to equip herself to do so. At present parents often fail to give this teaching, the poorer classes having no vocabulary and the better educated being reluctant to embark on the subject. The doubt was raised whether even the present-day parent is likely to be able to answer questions without affective tone, but the majority of contributors believed that she could be taught to do so. As to older children, the impression given was that a definite programme of sex instruction in schools would not be welcomed by the majority of parents in Norway, England, Hungary, and Spain, whereas parents in Sweden, Germany, and Switzerland are complacent if not eager for such instruction. In France opposition to any innovation comes from those parents who have no experience of modern methods of instruction. In this connexion it is interesting to note the attitudes taken in official circles in different countries. For example, in Norway the State does not encourage the authorities controlling the universities, training colleges, or schools to provide sex instruction in any form. On the contrary, those who have attempted such teaching have met with some resistance, and permission to use a text-book—described as "very good"—of health instruction containing a brief introduction to sex hygiene has been withheld. Of the other countries, the attitude in Germany forms the greatest contrast. Thousands of private as well as public lectures are given annually. Among the sections of the community who organise lectures are party political associations, associations of housewives, the trades-unions, associations of landlords, and religious organisations. Elementary and secondary school teachers attend compulsory courses in sex hygiene and in the recognition and guidance of psychological manifestations of sex instincts in adolescents. Chairs for sexual pedagogics are established at three German universities.

Some pertinent suggestions were made at the congress by various delegates. It was generally held that sex instruction to the young should form

Part of a group taken at the Clinique Baudelocque (Maternité). Prof. Couvelaire in centre.

part of courses of biology, anatomy, and physiology or hygiene and should not be given a special prominence. The deliberate omission of the reproductive system from consideration in any classes where structure, functions or hygiene of the other systems of the body are being explained is still the custom in some text-books and classes and is to be condemned. Several contributors stressed the mistake of giving different information to boys and girls, on the grounds that a single standard of knowledge is conducive to a single standard of morality.

The other subject discussed was

Analgesia in Midwifery.

Reports on this subject were collected by Dr. Doris Kunckel (Germany) and by Dr. Nechkovitch-Voutchetitch. All the contributors were agreed that there exists at present no ideal method of inducing analgesia in midwifery. Those which produce complete analgesia are not free from danger either to mother or child, or from unfavourable effects on uterine contractions. On the other hand, nearly all those replying to the questionaire agreed that even if the pain of labour is physiological and not pathological—a point on which there is no unanimity—every effort should be made to find harmless means to relieve it. The main drawback of inhalation anæsthesia is that it can only be applied in the second stage of labour, and even then, in its most usual form, chloroform and ether, only for a comparatively short spell. Opinions as to the advantages and disadvantages of chloroform and ether revealed no surprises, but considerable variation in practice. In France chloroform is popular and also a mixture of ether (60 parts), chloroform (20 parts), and ethyl chloride (10 parts). Nitrous oxide combined with oxygen was praised by speakers from America, England, and Germany, since it is free from danger, rapid in action, quickly eliminated when administration ceases, has no toxic effects, and does not diminish uterine contractions. It can be used safely in cases of cardiac, pulmonary, and renal disease. It has, however, the serious drawback of requiring a large and cumbersome apparatus and a specially trained person for its administration, and is therefore only suitable for use in a hospital. Moreover, it has sometimes to be supplemented by ether or chloroform.

Lumbar and sacral anæsthesia were not recommended for normal labour. Paracervical anæsthesia—the injection of novocain-adrenalin solution into the tissues and into the os uteri, combined with injections into the pudic nerve and large doses of pituitary extract—is said by some to lead to such a degree of relaxation of the cervix and perineum that the child's head meets with no resistance. It is contra-indicated in cases complicated by fever, gonorrhœa, and pelvic inflammation. The method appears to be worth further investigation.

As to twilight sleep, notwithstanding the considerable amount of success achieved by this method, it has important drawbacks and is not likely to be universally adopted. Pernocton and avertin were regarded as still in the experimental stage.

The administration of an analgesic in the second stage in normal cases was advocated by most of the American, British, German, and Scandinavian contributors for humane reasons. The danger of diminishing the force of the pains, of thus prolonging labour, and increasing the proportion of cases requiring interference was not overlooked; but, on the other hand, pain itself may be the cause of delay, or its intensity may determine the decision to hasten delivery by forceps when this is not inevitable. Representatives of French, Italian, Polish, and Yugoslavian medicine reflected a definite tendency in these countries to deprecate the administration of anæsthetics in normal cases, on the grounds that none yet available is completely innocuous to mother and child.

Visits to Institutions.

During the congress visits were paid to various hospitals and institutions. Prof. Couvelaire escorted a large party round the Clinique Baudelocque, a maternity hospital where accommodation for antenatal work and infant welfare as well as for the actual conduct of labour is spacious and the equipment admirable. Specially attractive features are the glass cubicles in the waiting-rooms to avoid infection of one patient by another, and the fact that while mothers and babies may spend the first days of the puerperium together in cheerful wards, there is no general labour ward, each patient being delivered in the privacy of a single room. The department for septic cases is housed in a separate block and cases of venereal disease are also treated, before or after confinement, in a well-warmed and lighted department where their convenience as to times of attendance is studied. The Clinique Baudelocque is only one of many " maternités " serving different areas in Paris, but it is one of the most modern in design and enlightened in administration. As regards tuberculosis, this clinic works in collaboration with the Hôpital Laënnec which was shown to some of the members of the congress by Dr. Jules Marie in the absence of Prof. Léon Bernard. Here mothers in whom tuberculosis has been detected at the clinic or elsewhere are brought with their infants, whether or not the latter have a positive Pirquet reaction. The infants are installed in a ward on the ground floor and are kept as much as possible in the garden; the mothers, warded on the first floor, are said to derive some comfort from watching them from the balcony. After six weeks, during which the Pirquet reaction is carefully watched, temporary cottage homes are found for those children who remain healthy, since experience shows that if they show no signs of infection at this stage they are likely to remain well. Recently a ward has been allocated to tuberculous fathers of young infants, the children also being admitted for observation.

On the surgical side a visit was paid to the Salpêtrière, where Prof. A. Gosset described the surgical clinic of 250 beds under his control. His department consists of a clinic of the Faculty of Medicine, of an anticancer centre, and of the various laboratories and X ray departments necessary to a surgical department. The Salpêtrière is an admirable example of the adaptation of an old hospital to modern requirements and the beautiful buildings and gardens were envied by those who work in towns where hospitals have had to cover nearly all their spacious grounds with buildings.

An opportunity was taken to visit a new clinic for children, opened in February last by Mr. Loucheur, Minister of Labour and Hygiene. This clinic has been organised under the Red Cross by the Association des Dames Françaises and is situated at 146, Avenue de St. Ouen, near the centre of the industrial area of Paris. The clinic is under the direction of Dr. R. Massart, to whom its inception is due, and who is himself responsible for the surgical department Other services include medical, orthopædic, ear, nose, and throat, antenatal, and dental departments, and there are three cots where children can rest after tonsillectomy. An operating theatre, X ray department, and pathological laboratory complete the picture. This miniature hospital is evidently welcomed by the practitioners of the neighbourhood and patients who pay what small sums they can afford are already plentiful. Here, as in some of the larger hospitals, precautions are taken to avoid the spread of infection by glass divisions in the waiting and dressing rooms.

At the Pasteur Institute Dr. Calmette, and at the Institut de Radium de l'Université de Paris Prof. Regaud, received members, while visits were also paid to the Musée de l'Hôpital Saint-Louis and the Musée de Guerre du Val-de-Grâce.

Social Activities.

The success of the congress was due to the great enthusiasm of the Association Française des Femmes Médecins in devising a programme and in procuring for the members so many agreeable social amenities. From the opening session on April 11th, when the rector of the Académie de Paris and the hospitable director of the Institute in which the meetings were held welcomed the members, an international spirit of cordiality prevailed. The president of the Senate received members in the Palais du Luxembourg, the Municipality of Paris at the Hôtel de Ville. Parties were given by various women's organisations and a dinner by the Association Française des Femmes Médecins. The reception given by Mme. Thuillier-Landry on the evening preceding the official opening was an admirable way of breaking the ice. The cordial spirit in which all delegates and members were greeted was appreciated especially by those who came from remote countries. The congress broke up in the assurance that for the next five years the affairs of the Association would be in safe hands and that its prosperity and influence would be still further extended.

CRIME IN ENGLAND AND WALES.

THE STATISTICS FOR 1927.

THE annual criminal statistics for England and Wales do not appear very punctually. Those for the year 1927 (Cmd. 3301, H.M. Stationery Office, 4*s.*) have just been issued by the Home Office. They give the first information of the working of the two important statutes which in 1926 amended the law of coroners and of death registration.

Coroners and Death Registration.

These two Acts have cost the country slightly more. Deaths rose from 54,111 in 1926 to 60,511 in 1927, but expenses rose from £67,123 to £93,666. No one will grumble if this means that, as Parliament intended, the coroner is getting more expert assistance in his task of investigating the cause of death. Full advantage is apparently not yet being taken of the facilities in this direction. The 1926 Act authorised coroners to obtain a post-mortem examination and report by a qualified practitioner and, if thereupon satisfied that no further inquisition was necessary, to dispense with an inquest except where there was cause to suspect violence or unnatural death and except in the case of deaths in prisons and other special circumstances. The Home Office comments on the fact that in one English and four Welsh counties and in 22 English and two Welsh boroughs no advantage was taken in 1927 of this machinery. The actual totals of post-mortem examinations requested or directed by coroners were 12,904 in inquest cases and 3616 in non-inquest cases. Increasing motor traffic presumably accounts for the upward trend in deaths due to accident. In 1927 as many as 15,135 deaths were attributed by coroners' courts to accident or misadventure—nearly 2000 more than in 1924.

The Increase in Suicide.

Suicide is another phenomenon which is increasing out of all proportion to the increase of population. The comparative figures here are startling. In 1856 there were 1314 cases; if the figure of suicides had merely kept pace with the figure of population, the total for 1927 would have been 2711, whereas in fact it was 4863.[1] It would be interesting to know whether the medical profession has been conscious of any such increase and, if so, to what causes it is to be ascribed. No great rise was noticeable before 1914; during the war there was a sharp fall in the rate; but since the last stages of the war there has been a swift leap from under 3000 to over 4500 suicides a year. The attempted suicide, it is noted, is being humanely treated. The first object is to find some relative or friend who will undertake to look after the person who committed the attempt. The Home Office discloses the fact that for many years it has advised police forces not to proceed against the accused where this object is attainable, unless there is some special reason such as the commission of a crime, threats to renew the attempt, previous attempts, habitual intemperance, or indications of insanity. In the last-named circumstances it may be essential that the accused person should, in his own interests, undergo a period of detention under skilled supervision. Here there is another change in the law to be mentioned. Three years ago (as the result of the Criminal Justice Act, 1925) it became possible to dispose of a charge of attempted suicide at petty sessions instead of, as formerly, to go to the expense, delay, and publicity of committing the accused for trial on indictment. The magistrates, therefore, can now impose a sentence of detention, and this course was taken in two-thirds of the proceedings in 1927, while, for the humane reasons already mentioned, no proceedings at all were taken in 1970 out of the 2724 cases of attempted suicide of which the police became aware. The "sex and age" table shows the usual disproportion between the totals of males and females on whom inquests were held. About twice as many inquests are held on males as on females; the figures for 1927 are 21,555 males and 10,872 females; in 1924 the respective figures were 20,849 males and 10,852 females.

Infanticide.

Inquests were held on the bodies of 276 children suffocated whilst in bed with their parents or others; in 22 of these cases an open verdict was returned, in the remainder the verdict was accidental death. There were 485 inquests on the bodies of newly-born children; in 28 cases a verdict of wilful murder was the result, in one case it was manslaughter, and in six cases it was infanticide. The usual introductory note to the criminal statistics by a member of the Home Office establishment draws special attention to the five years' working of the Infanticide Act of 1922. The Act seems undoubtedly to have achieved its purpose of diminishing the charges of murder against women who kill their babies while mentally deranged by recent childbirth. On the other hand, juries who before 1922 were inclined to bring in verdicts of mere concealment of birth instead of murder now seem willing to find verdicts of infanticide rather than concealment of birth. Of seven women convicted of infanticide in 1927, four were bound over without supervision, one was sentenced to 15 months' imprisonment, one to 12 months, and one was sent to an institution for mental defectives. Next year the writer of the introductory note might usefully enlarge upon the offence of criminal abortion. Recent prosecutions and the general practitioner's experience indicate that the official figures could be interestingly elaborated. The quinquennial averages for the present century of persons tried on indictment for procuring abortion have been 11 for 1900–04, 20 for 1905–09, 30 for 1910–14, and 43 for 1915–19. From 1920 to 1926 there were the following remarkable fluctuations: 35, 39, 19, 22, 44, 62, and 41. The 1927 figure was 44; 14 were men, 30 were women; 10 were acquitted, 1 was sent to penal servitude, 27 to imprisonment, and 6 were bound over. The statistics, of course, give no idea of the number of cases of strong suspicion taken up by the police.

LONDON ASSOCIATION OF THE MEDICAL WOMEN'S FEDERATION.—An open meeting will be held in the Hastings Hall, British Medical Association House, on May 3rd, at 8.30 P.M. A report of the Cancer Research Committee of the Marie Curie Hospital on three years' work on the treatment of cancer of the uterus with radium, with demonstrations of technique and cases, will be given by Miss M. Chadburn, Dr. G. Hurdon, and Dr. Helen Chambers. This will be followed by a discussion to be opened by Prof. Louise McIlroy, Miss E. Bolton, and Miss L. Martindale. The meeting is open to all members of the medical profession.

---

[1] In reply to a recent question in the House of Commons the Home Secretary gave the total figure for the year 1928 as 4845 (3381 males and 1464 females).

MODERN PHYSICAL TREATMENT IN RELATION TO RHEUMATISM.

BY R. FORTESCUE FOX, M.D., F.R.C.P.,
PRESIDENT OF THE LIGUE INTERNATIONALE CONTRE LE RHEUMATISME.

IN the present century physical treatment has undergone an unexampled development. Many kinds of energy have been utilised in medicine, one after the other. The long list of physical remedies now includes, in *radiotherapy*, radium and rontgen rays, Finsen's light, luminous and thermal, infra-red and ultra-violet rays, solar radiation and skyshine; in *movement*, exercises, manipulation, and mechanical treatment; in *electrotherapy*, besides the older forms, ionisation, diathermy, and the cautery knife; in *hydrotherapy*, a great extension of methods for applying heat and cold and mechanical energy in baths of water, vapour and hot air, not to mention local hyperæmia by heat or ligature.

So wide a therapeutic field naturally lends itself to irregular and partial exploitation; some one form of treatment, such as electricity, manipulation, or light is vaunted as the sole and sufficient cure. The popularisation of particular methods and the unfounded claims put forward by uninstructed persons gravely hinder the right development of physical treatment. It should be remembered, on the one hand, that this group of remedies, which are commonly called "natural," have always powerfully attracted both simple and educated people. On the other hand, it is equally true that from one cause or another a practical knowledge of their action and uses has not been included in the training given to medical men. Such a discrepancy between public demand and professional supply constitutes at the moment an evil which cannot be ignored. In the meantime the right attitude for the practitioner is well defined by a philosophical French writer:—

> "We are in danger of opposing our ideas the one to the other; progress in remedial exercises does not imply falling back in surgery; the use of waters does not oblige us to abandon the pharmacopœia . . . the specialist who tries to embrace too much injures his own speciality . . . the medical man who has only one means of treatment at his disposal is always poor, and sometimes dangerous. . . . That need not hinder us from carrying on our studies in one class of remedies, but it will prevent our giving to these remedies a disproportionate and above all an exclusive importance."[1]

Basal Facts.

The basal facts upon which physical treatment is founded are so familiar that they are almost forgotten. It is forgotten that life is maintained by a constant succession of physical stimuli, and that even the slightest changes in the physical medium are inevitably reflected in physiological changes in the organism. The human body, on account of its highly developed organs of contact, is almost incredibly sensitive to external conditions. Meteorological instruments can scarcely record changes of air of which many invalids are immediately aware.

It is true that young and strong persons can adapt themselves better than most animal and vegetable species to variations of temperature and altitude. But this primitive human power of acclimatisation to all kinds of physical conditions is usually at least in abeyance in civilised communities. It can be recovered in vigorous persons and by special training, but it is very much and permanently circumscribed in the majority of individuals. Intolerance of cold is met with at the two extremes of life, in infancy and in old age, often indeed beginning in middle life, also in certain races, and in susceptible but otherwise sound persons at all ages, in many states of depressed or failing health, after acute illness, and above all in many states of chronic illness, such as the "rheumatic" diseases. Of many chronic disorders it is a very striking characteristic; the physiological reaction to cooling of the body which takes place at once in vigorous subjects is more or less absent. Persons so affected must, like delicate plants, be temporarily or permanently protected against uncompensated cooling or "chill."

When a normal adaptation fails a series of abnormal reactions generally occurs. For example, in a "frigo-sensitive" subject the effects of exposure to a cold and changeable climate include repeated lowering of the body heat, abnormal contraction of the superficial blood-vessels, and alteration of the distribution of the blood, with reflex disturbances of the nervous, digestive, metabolic, and eliminative functions. Another significant effect of lowering the temperature of warm-blooded animals is an increase of liability to many forms of microbial infection. On the other hand, if in the same frigo-sensitive subject external heat or friction are skilfully applied, the subnormal temperature of the skin and of the body is restored to normal, and the peripheral circulation, metabolism, and circulation are increased. So far, then, as the functional disorders provoked by external cold are concerned, it is clear that a curative influence may be brought into play which is akin to the provoking influence.

Speaking generally, the object of physical treatment is to bring physical forces into action upon the surface of the body, so as, by a new series of impressions, to produce favourable reactions within the body. The student of physical treatment has to explore these different forms of surface action and to endeavour to define their precise application in all states of defective and abnormal function.

Physical Treatment as a Whole.

The stimuli received by the body at any time operate not singly but as a whole. Further, they are in process of transformation, for one form of energy always generates another form of energy. The green leaf at a given temperature and moisture receives rays and transmutes them into chemical, thermal, and electrical effects. The normal skin also, like the green leaf, has the power of receiving and transmuting energy. Climate includes humidity, warmth, movement, radiation, electricity, and perhaps something more. The human body is able by its organs of contact to respond at the same time to all these external stimuli. Physical treatment provides a new physical medium, by means of which defective contacts are re-established between the body and the energy outside the body. The normal contacts of life and the integrity of the reactions which are essential to health are in this manner restored.

The optimum physical treatment gives the optimum physiological reaction. It is questionable whether this is ever effected by simply increasing a single kind of stimulus. It is generally produced by a series of harmonious and increasing impressions of more than one form of energy. Thus, in an effervescent or carbonic acid bath the relative external heat and mechanical and chemical stimulation in the gas are combined with relative cold in the water, acting over constantly changing areas in the skin, the whole making up a special form of circulatory stimulation. Again, a light bath in the Alps combines an extreme degree of cold with unusual radiant energy. In a sea or surf bath all these elements are united in varying degree.

The resultant of impressions may be considered as *sedative* or *stimulant*. Baths and climates are regarded as stimulant if they increase, and sedative if they diminish, nervous and circulatory activity. But in practice more often than not both sedative and stimulant effects can be traced under all forms of physical treatment. In practice, especially in the treatment of rheumatic conditions, sluggish reactions in one part are often stimulated at the same time that over-action in another part is allayed.

It is, moreover, worthy of note that mental effects follow physical causes. The Aberdeen philosopher, Bain, used to say: "Heat is a typical form of passive physical pleasure."

---

Dosage.

Duration is the "fine adjustment" of dosage and should be precisely governed by individual reaction. It is known that thermal applications given in series produce in favourable cases better and more rapid reactions as day follows day. The new phase of circulation following thermal baths may continue for several hours with little change, and, if the patient is not chilled in the interval, this improved phase may not be entirely spent before the next bath. For this reason chronic maladies in particular are often benefited by a properly dosed and spaced course of applications, given in specially warmed buildings and spread over several weeks. After such a course a lasting improvement in the response of the body to external stimuli is often obtained.

A course of such treatment is tantamount to providing an artificial climate, the operative factors of which can be varied at will. Although the change of surroundings can be only temporary, the activity of the physiological response is so great that results are produced quite out of proportion to the duration of the stimulus.

Examples.

Many examples could be cited to illustrate the changes in the deep parts that may be effected by surface actions.

1. A bruised or wounded limb becomes cold and dusky, with tender and painful swellings or scars, unresolved exudations, and increasing limitation of power and movement. If such a limb be subjected to a bath of whirling or agitated water at 112° to 115° F. the arteries and capillaries dilate and the immersed part takes on a rosy pink colour. The scars and muscles can now be freely manipulated without pain, the joints moved more easily than before, and with repeated treatment the processes of healing and resorption are greatly accelerated.

2. Another example of both cutaneous and deep reactions is afforded by subthermal baths, such as are given as a sedative measure for mental cases. During the war they were used in England as "sedative pools" for conditions of nervous and mental shock. Men so affected were as a rule restless, often sleepless, with subnormal deep and surface temperatures, and a small rapid pulse. They were made to recline for an hour or more in gently flowing water at from 92° to 94° F., according to the season. During the bath the heart's action became slower and more tranquil, the surface and deep temperatures returned to normal, and sound sleep followed.[2]

3. The effervescent bath also, given at subthermal temperatures, is often of great assistance in cases of myocardial weakness with a chilly skin and contracted arteries. During the bath the radial artery may be observed to dilate, the pulse to become slower and stronger, and the parts immersed to flush from relaxation of the capillaries. This is an illustration of the autonomous reaction of the cutaneous capillaries to physical impressions, described by Krogh.

4. An impressive example of deep reaction to surface stimuli is seen in the effect of cold upon metabolism. The exposure of the body to moderate degrees of cold, in baths or fresh air, may in health much more than double the activity of metabolism. Leonard Hill, among others, has shown how important such facts have become in the treatment of chronic disease, and that cooling of the body is one of the most powerful of therapeutic weapons.

5. Winternitz, in his last published paper, set forth his experience of the use of cold in tuberculosis, and formulated rules for its application. It is only in the present century that it has been recognised that this infective disease, in whatever part of the body it may be situated, is best treated not by specific but by physical remedies. It should, moreover, be noted that in tuberculosis these remedies act best not singly but when judiciously combined after the pattern of Nature, as when radiant energy is conveyed to the body cooled by moving air or water.

The Physical Physician.

The reader may now be prepared to agree with Vierordt that the serious study of physical treatment marks a turning-point in the history of medicine. The work of reclaiming this field of practice was begun by clinical physicians in the last century. The trained and qualified physical physician will have for his special task the investigation and treatment of incipient and chronic diseases. He belongs to the school which pursues the study of disordered functions. He finds the nerve centres irresponsive or oversensitive; the blood-vessels, in general or in particular areas, contracted or relaxed; the normal distribution of the blood displaced; the rhythm of the heart or of the digestive functions disturbed; there are failures of elimination; metabolism is increased or diminished; the equilibrium of body heat is lost; the resistance to infection has lapsed. He believes that disturbances of function such as these are characteristic of chronic disease, and experience teaches him that, as van Leyden said, these disturbances are more amenable to physical remedies and change of habit and of diet than to drugs. His concentration of mind upon the functional element in all disease obliges him above all to investigate and measure the reactions to external impressions, because the character of these responses, changing from day to day, furnishes the key both to his diagnosis and to his treatment. His rôle is therefore that of a therapeutic research worker.

[*Subsequent articles will be devoted to continental practice and teaching and to the physical treatment in rheumatic diseases.*]

SCOTLAND.

(FROM OUR OWN CORRESPONDENT.)

The Backward Child.

FIFE is one of the most important educational areas in Scotland and any facts about it are likely to be paralleled elsewhere. Much significance therefore attaches to observations made in this county which are described in the annual report of the Scottish Education Department. It appears that of the pupils who left school in 1926–27 (excluding those who died, migrated, or were untraced) 64 per cent. left without having completed two years of post-primary education—that is without having qualified even by attendance for the award of the day-school certificate (lower). This certificate is the leaving certificate of the day school; as such it should be obtainable by any pupil of normal ability who has been in regular attendance at a day school up to the statutory age and has worked with ordinary diligence. Yet 64 per cent. fail to qualify for it. Others leave from the senior division without ever participating in any form of post-primary education. The chief causes of the retardation are said by the teachers to be, in order of frequency, lack of ability, migration, ill-health, low power of application, late enrolment, irregular attendance apart from health, and unsatisfactory home conditions. It is hinted that a jury composed not entirely of teachers and headmasters might possibly have added other items to this catalogue.

To speak generally, not more than from 10 to 12 per cent. of our school-children, including mentally defective children, are of less than normal intelligence; yet 64 per cent. fail to reach the stage of the day-school certificate (lower). What is needed as a remedy is individual attention by a patient, intelligent, and sympathetic teacher. But behind this there is the question whether we are not asking too much of the average child of 12. Suggestions are made for "a very slight lightening of the ship." This raises the question of the functions of the secondary schools. There is a growing disposition on the part of parents to secure to their children the advantage of the secondary schools; but owing partly to this leakage from below and a further leakage at the secondary school stage, "the proportion desiring a leaving certificate was extremely limited."

---

[2] Fox, R. F.: Physical Remedies for Disabled Soldiers, London, 1917.

This report is a very important deliverance, since the whole problem of the higher education is based upon the leaving certificate. Knowing the long history of struggle and difficulty in the establishing of the leaving certificate as an active method of maintaining the intellectual standard, I can only regret this note of pessimism; but, on the whole, to those that have known Scottish education for 50 years, the wonder is that the certificate has been so successful. As the psychological experts are now getting a better grip of educational conditions, there is a tendency to belittle "examinations" as a mental test; but this is only a passing phase. In actual practice, the examination test, in the past generations, has worked wonders, and if in later years it has become over-exacting, this is merely a defect of every such general method of testing. One cannot but revert to the same struggle in Germany nearly 100 years ago. A full account of it is given in Matthew Arnold's "Schools and Universities in Germany." This book is probably not now read very widely; but it was one of the stimulants that led to the British equivalent of the German leaving certificate (Abiturienten examen). In Germany the specialisation of the schools probably began at too early a stage and became too rigid; but there can be no question that the elaborate scheme framed by von Humboldt originally did place German secondary education on an extraordinarily efficient basis. The Scottish system had to rest on a different type of existing school; but, on the whole, the results must be pronounced good. No doubt the special problem emerging at the end of the elementary school course will now receive much more detailed attention and we may hope that the results will be satisfactory. The economic question is troublesome; but many forces are now converging to persuade the general public that the condition of education beyond the elementary stage is one of the cardinal methods of preparing an efficient people and, in the end, of improving economic conditions.

Hospital Amalgamation.

The annual report of the Edinburgh Royal Maternity and Simpson Memorial Hospital states that the total number of cases treated last year was 3205, compared with 3117 in the previous year. As regards the proposed amalgamation with the Royal Infirmary, some progress has been made. The report points out that it is generally recognised that the situation has considerably altered since Nov. 16th, 1923, when the project of amalgamation was first mooted, owing first to doubts which have arisen as to whether the provision of maternity service is not the province of the State rather than of the voluntary hospital; and, secondly, the possible effect of the De-rating Bill. Committees representing the Royal Infirmary and the hospital have discussed the maternity problem in Edinburgh, and how many beds the managers of the Royal Infirmary should be expected to provide in the new buildings to be erected on the site of George Watson's School, and have arrived at the conclusion that not less than 120 beds are needed.

Dr. A. S. Macgregor, medical officer of health for Glasgow, has issued a circular to owners and occupiers of premises which are liable to rat invasion, calling attention to the fact that since the Rats and Mice (Destruction) Act, 1919, came into operation an endeavour has been made by the Department of Agriculture for Scotland to inaugurate a rat week in the spring of each year, a period when repressive measures are most likely to be successful. Dr. Macgregor says that the services of the inspectors [illegible]ic Health Department, in an advisory [illegible] made available to any person wishing

IRELAND.

(FROM OUR OWN CORRESPONDENT.)

Urgent Health Problems in Ireland.

Dr. E. E. Stephenson, the Chief Medical Adviser of the Department of Local Government and Public Health, acts wisely in taking the public into his confidence from time to time about the health problems which are of importance to the country. Last week he gave a useful and informative interview to the press. Among other things he stated that there was an urgent necessity for the appointment of county medical officers of health in the various counties where such appointments had not yet been made. Whilst the novelty of the situation and adverse financial circumstances had caused delay, further delay could not be condoned. There was no county in the Free State, he said, that was without special health problems calling for solution. Among those of the most pressing importance were the eradication of typhoid fever and diphtheria, the prevention and correction of crippling, the reduction of infant mortality, and the protection of women against the special dangers associated with childbirth. In some counties, notably Limerick and Monaghan, the maternal mortality-rate was so high as to establish an incontestable need for organised supervision over midwifery practice. Certain chronic areas of typhus infection, notably in Kerry, Galway, and Donegal, were not alone a danger to the community, but a reproach to the public administration and a menace to the credit of the country. Again the recent disastrous experiences at Carrick-on-Shannon, where some 50 people contracted typhoid fever from a contaminated water-supply, was largely due to the absence of an expert controller of the public health services. Dr. Stephenson drew attention to the high mortality in Ireland from heart disease, much of which was preventable. The early discovery of the conditions leading to heart disease could be secured by medical inspection of school-children. With regard to trachoma and other causes of blindness he said that the pensions payable in the Irish Free State on account of blindness due to preventable causes amounted to £10,764 a year. Among 12,000 children inspected in Dublin 7000 suffered from defects, of whom 5000 required immediate treatment.

Irish Medical Association.

At its last meeting the council of the Irish Medical Association nominated Mr. P. E. Hayden, Vice-President, for election as President. Mr. Hayden is surgeon to Jervis-street Hospital, and a member of the Council of the Royal College of Surgeons in Ireland. The Council nominated Dr. Eugene Byrne, of Slane, Meath, for the Vice-Presidency. He is a very old member of the Association and has been a member of the Council for several years.

PARIS.

(FROM OUR OWN CORRESPONDENT)

The "Tuscania" Incident.

THE steamship *Tuscania* and her passengers ill with small-pox have not roused in France as much interest as in England. In fact, were it not for the diplomatic side, the incident would have been considered of little importance. The reason is simple. In France vaccination against small-pox is not a matter for discussion; it is an accomplished fact. There may be a few doctors who, in theory at least, consider that vaccination may under certain circumstances be harmful or ineffective. But even they do not always accept the responsibility of forbidding vaccination in their practice or among their own family. No case of the kind has occurred, but it is certain that a court of law would award big damages against the family doctor if a child died of small-pox under his care, and it was established that he had forbidden vaccination. French law makes vaccination compulsory for every infant before completing its second month of life, and fines its guardians in case of default.

Laws are accepted in France only if they are justified by necessity and use, and this is certainly the case with compulsory vaccination. The last real epidemic of small-pox occurred in France during the war of 1870–71. Shortly afterwards vaccination was made compulsory, and nothing hindered the execution of the law, for everyone had in mind the dreadful remembrance of the small-pox fatalities among the civilian and military population during the Siege. Nor has this been forgotten since. The first thing that happened in 1914 after the departure of the troops towards the frontier was the vaccination of the civilian population, creating the first queues at the gates of hospitals or dispensaries. If the facts are analysed further it is realised at once that small-pox in France is a particularly severe disease and has been so throughout the whole history of the country. Case mortality has rarely been under 50 per cent. and has reached 80 or even 90 per cent. in certain epidemics. This explains much. The figures are in complete contrast with those gathered in English statistics, but they are nevertheless quite trustworthy. The same fear of consequences ensures that every case of small-pox is registered and nearly all are sent to hospital, so that it cannot be argued that only severe cases are registered. There is no doubt on this point, and I have often observed, even in the Indian statistics, a similar difference in mortality between the five French towns and the British towns of the same land, as given by the Health Committee of the League of Nations.

What is the efficiency of the compulsory vaccination law? To this question every Frenchman (with the exceptions mentioned above) will answer that the law is perfectly efficient—if it were not, the law would have dwindled out of use, as it has almost done for the compulsory notification of measles. In addition to the compulsory vaccination of infants, new vaccination is exacted for entrance to school, to military service, before taking up work in public or private offices, at matriculation for universities, and so on. Hence at several points of life new vaccination becomes an obligation by the simple mechanism of public life. In case of epidemic, actual or threatened, powers have been given by law to the *maires* of each town or borough to render vaccination compulsory for all inhabitants, whatever their age. The *préfets*, who are at the head of the administration of each department (county), have powers of compulsion should the *maire* default.

At the present time there are hardly any cases of small-pox in France. When cases do occur it is invariably because there has been some neglect in the application of vaccination, and the epidemic is stopped at once by immediate vaccination of the surrounding population. In fact, were the French territory closed in by a Chinese wall, small-pox would never be seen. Nearly all the cases are foreigners who have escaped vaccination, for the most part natives from North Africa or Spaniards, who are always ready by some trick or other to elude collective vaccinations at the frontiers. One thing is certain; there is no chance for tourists in France to catch small-pox unless they hire a weekly room in the filthy slums where the immigrants dwell on their arrival, and even there the chance is small.

Anti-Diphtheria Vaccination.

Though inoculation against typhoid is compulsory in the army, small-pox is still the only disease against which civilians in France are obliged to be immunised. Two years ago the Government explored the possibility of compulsory prophylaxis against diphtheria, but it was generally agreed that any legislation to this effect should be postponed, official aid being meanwhile granted to propagandist measures. The mode of vaccination is by the anatoxin (formolised toxin), studied in France by Ramon, one of the heads of the Pasteur Institute. This has been investigated clinically by Prof. Lereboullet with his assistants, especially Dr. Gournay, and by Prof. Zoeller, of the military school of the Val-de-Grâce. The Pasteur Institute furnished 15,000 doses of anatoxin in 1925 and 300,000 in 1928.

The Ministry of Health has embarked on a special "week of propaganda for diphtheria vaccination" which began last Monday with the broadcasting of a short lecture by the Minister himself, Mr. Loucheur, in which he called attention to the fact that every year 3000 children die from diphtheria and that this could be prevented by inoculation. Special lessons on the subject are being given in every school in the hope that the children will repeat at home what has been told them and that the teaching will thus reach the parents. Lectures are to be broadcasted, and newspapers throughout the country are publishing special articles to spread the gospel of immunisation against diphtheria.

Public Health Services.

INFECTIOUS DISEASE IN ENGLAND AND WALES DURING THE WEEK ENDED APRIL 13TH, 1929.

Notifications.—The following cases of infectious disease were notified during the week:—Small-pox, 339 (last week 273); scarlet fever, 1764; diphtheria, 962; enteric fever, 32; pneumonia, 1743 (last week 2158); puerperal fever, 44; puerperal pyrexia, 111; cerebro-spinal fever, 20; acute poliomyelitis, 3; acute polio-encephalitis, 1; encephalitis lethargica, 23; dysentery, 9; ophthalmia neonatorum, 112. No case of cholera, plague, or typhus fever was notified during the week.

The cases of small-pox were notified from the following 26 counties: London, 29 (viz., Bethnal Green, 8; Kensington, 2; Lambeth, 1; Paddington, 1; Poplar, 3; St. Marylebone, 1; Stepney, 10; Wandsworth, 2; Westminster, 1); Cambridge, 1 (Borough); Chester, 1; Derby, 18; Durham, 42; Isle of Ely, 3; Essex, 26 (viz., East Ham, 1; West Ham, 23; Grays, 1; Chelmsford (R.D.), 1; Huntingdon, 4; Kent, 2 (viz., Gillingham, Gravesend, 1 each); Lancaster, 13 (of these Leigh, 6); Leicester (C.B.), 1; Lincoln, Parts of Holland, 4; Parts of Lindsey, 1; Middlesex, 5 (viz., Acton, 2; Edmonton, 1; Hendon, 1; Willesden, 1); Northampton, 39 (of these County Borough, 38); Northumberland, 6; Nottingham, 1; Peterborough, 7 (Borough); Stafford, 44 (of these Stoke-on-Trent, 42); Sussex East, 2 (Brighton); Wilts, 15 (Swindon); Worcester, 1; Yorks, West Riding, 33; Brecknock, 3; (Brynmawr); Glamorgan, 26; Monmouth, 11; and from the Port of Cardiff, 1.

The number of cases in the Infectious Hospitals of the Metropolitan Asylums Board on April 16th–17th was as follows: Small-pox, 200 under treatment, 10 under observation (last week 192 and 10 respectively); scarlet fever, 1501; diphtheria, 1707; enteric fever, 12; measles, 103; whooping-cough, 1102; puerperal fever, 20 (plus 5 babies); encephalitis lethargica, 79; poliomyelitis, 4; "other diseases," 58. At St. Margaret's Hospital there were 14 babies (plus 8 mothers) with ophthalmia neonatorum.

Deaths.—In the aggregate of great towns, including London, there was 1 death from small-pox, 1 (0) from enteric fever, 58 (0) from measles, 6 (2) from scarlet fever, 120 (40) from whooping-cough, 39 (6) from diphtheria, 48 (12) from diarrhœa and enteritis under two years, and 247 (47) from influenza.

The death provisionally classified to small-pox was assigned to Acton (M.B.) Great towns reporting 10 or more deaths from influenza were Birmingham 21, Manchester 12. Liverpool reported 19 deaths from measles, Cardiff 7, Birmingham 6. From whooping-cough, Manchester reported 10 deaths, Liverpool 6, and Salford 5. No great town reported more than 5 deaths from diarrhœa.

Deaths from Small-pox.—The fatal case of small-pox reported at Acton was that of a woman, aged 28, four months pregnant in her third confinement. Dr. D. J. Thomas, medical officer of health for the borough, informs us that she joined the *Tuscania* at Port Said on March 23rd, landed at Liverpool on April 1st, and reached her home in Chiswick the following day. She had not been vaccinated since infancy. She became ill on April 5th, with a temperature of 101° F., and backache which was attributed to the pregnancy. She aborted on April 8th, but the pain in the back persisted. On April 9th her doctor received a telephone message that she was dead. On examination he noticed a purpuric rash round the groin, and asked Dr. Thomas to see her. The doctor had not been informed by the patient's friends that she was a small-pox contact, nor had the public health department been notified that she was ill, though inspectors from the department had visited the house and inquired as to her welfare. Dr. Thomas found a purpuric rash on both groins extending on the right side as far as the axilla, there was subconjunctival hæmorrhage, and the beginning of a focal rash (two spots) on the right forearm. On the same day the husband, who was ill, was seen by Dr. Thomas, who found a rash just coming out and becoming confluent. He died on April 16th at Joyce Green Hospital, Dartford.

The number of stillbirths reported during the week was 299 (corresponding to a rate of 40 per thousand births), including 54 in London.

THE NEW IMPORTANCE OF RADIUM.

To the Editor of THE LANCET.

SIR,—In the report of the Radium Subcommittee of the Committee of Civil Research, which you summarised last week, allusion is made (p. 5) to the so-called "surgery of access," which has sprung into existence as the value of radium in medical treatment has been progressively recognised. "We do not doubt," the report states, "that as further knowledge is obtained in regard to the possibilities of this radium-surgery, its use will develop rapidly, and in an increasing measure it will replace the use of the knife in the treatment of cancer." Personally I think a statement like this is likely to mislead not only the public but the medical profession. The main point is whether in the first instance a tumour is susceptible or not to irradiation. Obviously surgery which provides access to a tumour is not going to influence this. Secondly, surgery of access only enables a localised method of treatment to come into play. The logical development of our present-day knowledge is the use of large quantities of radium at a distance from the body, which enables a wide field to be covered and a fairly homogeneous intensity of irradiation to be given to a moderate depth below the surface of the body.

I am, Sir, yours faithfully,

G. E. BIRKETT.

Manchester and District Radium Institute,
April 20th, 1929.

THE "PHYSIOTHERAPY CLINIC" AND THE PRACTITIONER.

To the Editor of THE LANCET.

SIR,—Dr. Ray's letter in your last issue calls for comment. To my mind physiotherapy is too wide a term. It should surely be divided into balneology and electro-therapeutics, the latter requiring skilled and qualified operators. In a leading article which you published some months ago on unqualified electro-therapeutists you called proper attention to this crying evil. Before then I myself had drawn the attention of Dr. Ray and others to the proper remedy for this dangerous practice, which can only be stopped by legislation. The political section of the British Medical Association has, I am glad to say, taken the matter up and it will be pushed through in due course. My suggestion was that no one should be allowed to carry out such treatment unless he had passed a thorough examination in the physics of electro-therapeutics and held a certificate to that effect issued by a proper board of examiners. Then, and only then, will doctors be justified in sanctioning such treatment at the various institutions. Meanwhile they must find time to treat their own patients and to charge accordingly.—I am, Sir, yours faithfully,

W. S. WHITCOMBE.

Harley-street, W., April 20th, 1929.

FUNCTIONAL NERVOUS DISORDERS IN THE SERVICES.

To the Editor of THE LANCET.

SIR,—I was somewhat surprised to notice that in the discussion at the Royal Society of Medicine (War Section) on April 8th (reported in your issue of April 13th, p. 773) no mention was made of the examination of the teeth. Apart from the presence of oral sepsis it is recognised that in certain cases unerupted and impacted molar teeth may, by reflex irritation from pressure of the second molar, be the causal factor of such conditions as neurasthenia, hysteria, chorea, epilepsy, or even insanity. This suggests to my mind that routine radiographic examination of the teeth would assist the diagnosis and indicate a line of treatment. Many cases in which such impacted molars have been found and extracted have greatly improved, and a certain percentage have completely recovered. I know of a physician who, acting as honorary medical adviser to a missionary society, has stipulated that all candidates shall have dental radiograms taken before they are finally accepted as he is convinced that, if the large number of Europeans who are employed and reside in the East had such an examination carried out, many cases of so-called tropical neurasthenia would never occur.

I am, Sir, yours faithfully,

J. D. KIDD, M.B., Ch.B., D.M.R.E. Camb.

Cavendish-square, W., April 22nd, 1929.

INQUIRY INTO THE ÆTIOLOGY OF CANCER

To the Editor of THE LANCET.

SIR,—In THE LANCET of June 16th last (p. 1250), an appeal was made to your readers to help in a statistical research into the ætiology of cancer, by answering a schedule of questions relating to a cancer patient and a non-cancer patient of the same sex and about the same age as control case.

The response to this appeal, though somewhat disappointing, was sufficient to justify printing the schedules and starting the investigation, and some medical practitioners have rendered most useful service by their careful work in completing these forms. In order that sufficient data may be secured more volunteers are needed, and since many of your readers doubtless did not see or give careful consideration to the first appeal, may I again ask that any who are in touch with cases of cancer, whether in general, specialist, or hospital practice, and who are prepared to devote a few hours to assist in this research, will communicate with me at the Galton Laboratory? Unfortunately, it is not possible to offer any kind of remuneration for this service, but I feel sure that there are some who will be prepared to make this voluntary sacrifice of a little time to help in a form of cancer research which can only be carried out by team work.

I am, Sir, yours faithfully,

PERCY STOCKS, M.D., D.P.H.,
Reader in Medical Statistics, University of London.

Galton Laboratory, University College, London, W.C.,
April 23rd, 1929.

THE ÆTIOLOGY OF UROLITHIASIS.

To the Editor of THE LANCET.

SIR,—In your issue of April 20th (p. 847) Dr. Levick says that he does not think that Europeans in the tropics suffer from urolithiasis as the result of excessive exposure to the solar ultra-violet rays. I have no doubt that Dr. Levick is right and, so far as

I know, Europeans in the tropics do not suffer from urolithiasis to a greater extent than their fellows in temperate climates. My suggestion referred to the natives who compose an overwhelming proportion of the populations in tropical countries and who from the nature of their clothing are exposed to the full effects of the ultra-violet rays. This applies especially in the case of children who are also, I believe, the worst sufferers from urinary calculi. Reliable statistics relating to the incidence of calcium phosphate stones in tropical countries are difficult to obtain; but it would be interesting to compare the relative frequency of stone in the European and native populations over a large series of cases. I do not suggest that excessive exposure to ultra-violet light is the only cause of the condition. No doubt sweating and other factors play a part in the ætiology of tropical urolithiasis, but the production of urolithiasis in experimental animals by irradiated ergosterol suggests that further investigation along such lines might throw valuable light on the influence of excessive solar irradiation in producing urinary calculi.

I am, Sir, yours faithfully,

J. CLIFFORD HOYLE.

Pharmacological Laboratory, University of Cambridge, April 23rd, 1929.

Obituary.

SIR GEORGE ADLINGTON SYME, K.B.E.,
M.B. MELB., F.R.C.S. ENG.,

FIRST PRESIDENT OF THE AUSTRALASIAN COLLEGE OF SURGEONS.

WE regret to announce the death of Sir George Syme, President of the College of Surgeons of Australasia, which has been announced by telegram during the week.

George Adlington Syme was born on April 13th, 1859, the son of Mr. George Alexander Syme, and was educated at Wesley College, Melbourne, the University of Melbourne, and later at King's College, London. He graduated in medicine at the University of Melbourne in 1881 and was for two years resident medical officer of the Melbourne Hospital. In 1885, being already M.R.C.S., he took the diploma of F.R.C.S. Eng., and returning to Australia became demonstrator of anatomy in the University of Melbourne in 1887, in which year he was elected out-patient surgeon to the Melbourne Hospital. In 1903 he became full surgeon to the institution, and held this position for 16 years, throughout which period he lectured, first on anatomy and later on clinical surgery, acting also as an examiner at the University in both subjects. He was also surgeon to the police force of the city and honorary surgeon to St. Vincent's Hospital. He was for many years a special correspondent of THE LANCET and was also a prominent supporter of the British Medical Association, being three times President of the Victorian Branch, and a frequent President of various sections at the annual congresses of the Association. He acted as chairman of the Royal Commission on Health for the Commonwealth of Australia, and in many other directions was recognised alike as a sound doctor and administrator.

On the outbreak of war Sir George Syme received a commission as Lieut.-Colonel in the Australian Expeditionary Force and became chief of the surgical staff of the first Australian General Hospital. Later he was appointed consulting surgeon to H.M. Hospital Ship *Gascon*, and at the close of hostilities retired with the rank of hon. colonel, becoming later a member of the medical advisory committee and consulting surgeon to the repatriation commission. In recognition of his military and public services he was created K.B.E. in 1924.

During the last two years Sir George Syme was deeply interested in the foundation and promotion of the Australasian College of Surgeons, and in the difficulties which beset the College on its inception he proved a brave and sincere advocate of the cause which he had at heart. The foundation of the College was viewed with considerable suspicion by many members of the British Medical Association, and by many general practitioners, who considered that the creation of an institution empowered to give an honorary degree might reflect on their own status, and indeed influence for the bad their professional earnings. The aim of the College as set out by Sir George Syme was to promote the art and science of surgery (using the words of the charter of the Royal College of Surgeons of England), and also to act as an organised scheme for post-graduate training in surgery either for graduates wishing to take a higher degree in surgery or for practitioners who with or without such a degree wanted to acquire or improve their surgical skill. The first annual meeting of the College took place in April, 1928, and considerable criticism was meted out to the scheme, but an address delivered by Sir George to the Victorian Branch of the B.M.A. went far towards reconciling adversaries; for he there warned his audience that the newly founded American College of Surgeons might prove a formidable rival unless an analogous institution arose in Australia. In the autumn of 1928 Sir George proceeded to Boston and received the honorary Fellowship of the American College.

Syme was respected and trusted by such a large number of friends and colleagues both within and without his country that his death leaves a real and widespread sense of loss. He is survived by his widow, the daughter of Mr. William Berry, of New Zealand, one son, and two daughters.

ALFRED TAYLOR SCHOFIELD, M.D. BRUX., M.R.C.S. ENG.

Dr. Schofield, whose death occurred at Bournemouth on Saturday last, in the eighty-second year of his age, was for many years known as an enthusiastic worker in support of health and educational causes. He was born in 1846 at Roach Bank, Rochdale, where his father, Robert Schofield, resided. He was educated at Elizabeth College, Guernsey, and entered the medical profession through the medical school of the London Hospital where he was a prizeman. In 1883 he took his conjoint diploma and a year later the M.D. with Honours of the University of Brussels. He practised for a considerable time in Harley-street, and a list of his public activities shows well the range of his sympathies. He was at one time chairman of the Parents' National Educational Union; he was a member of the Council of the Sanitary Institute, of the Royal British Nurses' Association, of the Church Sanitary Association, and of the District Nurses' Association. What may be styled domestic physiology and psychology, especially in their relation to women, were made the subjects of a large literary output; his handbook on personal domestic hygiene, and a volume treating of the borderlands of science proved acceptable to many readers. No one was a more enthusiastic preacher than Schofield of the truth lying behind the aphorism that cleanliness is next to godliness. Dr. Schofield married nearly 60 years ago Miss Frances Vaughan Jackson, by whom he had one daughter.

JAMES PRINGLE PARK INGLIS, M.D. EDIN.

WE have to record the death, on April 10th, of Dr. J. P. P. Inglis, deputy medical superintendent of Leavesden Mental Hospital, Watford, in his fifty-third year. He was the son of the Rev. R. C. Inglis and was born at Berwick, where he was educated at the Grammar School. Thence he went to the University of Edinburgh, and on graduating in 1905 became clinical assistant to the late Sir Thomas Clouston at the Royal Asylum. He later held a similar appointment in London at the West End Hospital for Nervous Diseases, and after experience in mental hospitals at Portsmouth and Canterbury, entered the service of the Metropolitan Asylums Board in 1909. In this service, with appointments at

Caterham, the Fountain Mental Hospital, the Darenth Training Colony, and lastly at Leavesden, he remained until his death, the only interval being caused by the war, during which from 1916–19 Dr. Inglis served with the Royal Army Medical Corps as Mental Specialist to the Forces in Egypt. For his work in this capacity he was mentioned in despatches. Dr. Inglis was married but leaves no children.

DUNCAN OTTO MACGREGOR, M.B. GLASG.

THE death of Dr. D. O. Macgregor, superintendent of Glasgow Victoria Infirmary, removes a well-known figure from medical circles in the West of Scotland. Sixty-one years of age, he was born at Tranent and was educated at Glasgow Academy, George Watson's School, and Berkhamstead School before going to study medicine at Glasgow University. In his college days he was a keen Rugby player. After graduating in 1890, he gained post-graduate experience at Leipzig and as resident house physician at Glasgow Royal Infirmary, and house surgeon at Glasgow Maternity Hospital and the Northern Infirmary, Inverness. Then he took up private practice, first at Cardiff and later in London, and it was with considerable knowledge of general medical work that he started his career as medical superintendent of the Glasgow Victoria Infirmary 29 years ago. In this new sphere his attention turned to the use of X rays and as radiologist to the hospital he later did a great deal in this special department. An able administrator of sympathetic personality, he was popular with both staff and patients. Outside his work at the infirmary he was deeply interested in Highland affairs, and especially in the Clan Gregor.

Parliamentary Intelligence.

NOTES ON CURRENT TOPICS.

LORD MOYNIHAN.

Lord MOYNIHAN (formerly Sir Berkeley George Andrew Moynihan, Bart., K.C.M.G., C.B.) was introduced with the customary ceremony in the House of Lords on Wednesday, April 17th, on his elevation to the peerage. His introducers were Lord Dawson of Penn and Lord Illingworth.

SCHOOL MEDICAL SERVICES.

The debate on the vote for the salaries and expenses of the Board of Education was opened on May 23rd by Lord EUSTACE PERCY, who spoke of the need for extending the scope and number of special schools and nursery schools. Mr. D. M. COWAN welcomed the establishment of an Educational Research Committee for Scotland, and Mr. JOHNSTON criticised the small amount of money spent in Scotland on the physical welfare of the child compared with that spent on education. Major ELLIOT spoke of the desirability of unification and amalgamation of health services, and promised to draw the attention of the Secretary of State for Scotland to the views of the Committee that greater attention should be paid to the physical condition of school-children.

HOUSE OF LORDS.

WEDNESDAY, APRIL 17TH.

LOCAL GOVERNMENT (SCOTLAND) BILL.

The Local Government (Scotland) Bill was considered on report.

Provisions Relating to or Consequent on Transfer of Functions.

On Clause 5 the Earl of ONSLOW (Paymaster-General) moved a drafting amendment to ensure that the section shall apply to a body such as the Royal Asylum of Montrose.

The amendment was agreed to.

The Earl of ONSLOW further moved after Subsection (2) to insert:—

> "Where in the constitution of any trust or other body whether corporate or not, provision is made for the appointment as trustees or members of the governing body of one or more members of a district board of control whose functions are by this Act transferred to two or more transferee authorities, the General Board of Control for Scotland may, after consultation with the trustees of governing body by order provide for the transferee authorities concerned jointly or a joint committee thereof or for the transferee authorities severally nominating trustees or members of the governing body in place of the members of the district board of control, and the constitution of the trust or other body shall have effect subject to the provisions of any such order."

He explained that this amendment was also designed to meet a case such as that of the Royal Asylum of Montrose where, under the constitution, the district board of control had a right to appoint representatives to the governing body. The district board would now disappear, and its functions were transferred to two separate authorities, the county councils of Angus and Kincardine. The amendment authorised the General Board of Control to provide that the appointment of these representatives should be made either by the two county councils jointly or by a joint committee; or so many appointments might be given to the one county council and so many to the other.

The amendment was agreed to.

Medical Officers of Health and Sanitary Inspectors.

Viscount YOUNGER OF LECKIE moved to leave out Clause 35, and to insert the following new clause:—

> "On a vacancy arising after the commencement of this Act in the office of medical officer of health or sanitary inspector of a small burgh, the medical officer of health or sanitary inspector, as the case may be, of the county within which the burgh is situated shall *ipso facto* become the medical officer of health or sanitary inspector for the burgh, and such proportion of the salaries and expenses of such officer as the county council and the town council may agree shall be paid by the town council to the county council, and, failing agreement, as may be determined by the Department of Health."

He said that his object was to introduce into the clause the post of sanitary inspector as well as the medical officer of health. It was very important that county sanitary inspectors in Scotland should in similar circumstances be always the sanitary inspectors of the small burghs. In that way they would get a much better official, a man of higher standing, of greater capacity, as well as a more independent man.

The Earl of ONSLOW said that the case in regard to the medical officer of health had been decided by their lordships, who had accepted the principle laid down in the Bill, but in regard to the sanitary inspector rather different considerations presented themselves. In some of the smaller burghs of Scotland at the present time only a very small sum was available for the payment of the sanitary inspector, and the consequence was that the sanitary inspector very often was a person who had not the qualifications which were laid down in Subsection (2) of the clause. The object of that was to ensure that all sanitary inspectors should be thoroughly qualified persons. In a burgh which had a sanitary inspector of its own, two sanitary inspectors would be concerned with the health services of the burgh. The county sanitary inspector would be concerned with the major sanitary services, and the burgh sanitary inspector would be concerned with the minor sanitary services, one being the matter of lodging-houses. It had been represented very strongly in Scotland by many of the smaller burghs, and it was eminently desirable that they should have a sanitary inspector to themselves, and those which had made this representation most strongly were the burghs which were seaside resorts. But if these burghs were to maintain sanitary inspectors they must be thoroughly qualified. If they could not afford to pay for such an official the burgh must come to an arrangement with the county. In all probability in such a case the county sanitary inspector would be appointed, but he did not say that it was absolutely necessary that he should be. He hoped that their lordships would accept the Bill as it stood in view of the strong feeling in the small burghs on the question.

The Earl of MAR AND KELLIE said that it was absolutely essential that the sanitary inspector should be a county official. The work of the medical officer and the sanitary inspector was interlaced and interwoven. They constantly had to carry out their duties together, and if they were appointed by two different authorities, and controlled by those authorities, there was bound to be friction. He hoped the Government would accept the amendment.

The Duke of BUCCLEUCH said he agreed with the noble earl who had just spoken that it was most essential for efficient administration that the amendment should be accepted. The health of the public throughout the county, including the burghs, should be the first consideration, and should come before any susceptibilities which might exist. It was perfectly well known that there had been cases in the past where the medical officer and the sanitary inspector had been at loggerheads, and the result had been, if not disastrous, at all events very unsatisfactory.

The Marquess of SALISBURY (Lord Privy Seal) agreed that it was of supreme importance that these sanitary services should be carried out by competent men. But that was provided by the Bill. No man was to be appointed henceforth who had not got a proper certificate. The sanitary inspector ought to be under the medical officer, but he would not be under him for all purposes even if Lord Younger's amendment was passed. In process of time probably those interested in Scottish legislation would see that the sanitary inspector was placed for all purposes under the medical officer of health. When that time came probably it would be a very good opportunity for the general reconsideration of the position. In the meantime the Government had met part of the difficulty.

The Earl of STAIR said he hoped that Lord Younger would press his amendment. The position of county councils was going to be difficult enough in taking over duties from different authorities without having to decide between existing sanitary inspectors in the smaller burghs. It was very desirable that there should be one sanitary inspector for the whole county.

On a division, Lord Younger's amendment was carried by 33 votes to 20.

The report stage of the Bill was concluded.

TUESDAY, APRIL 23RD.

Qualifications of Chemists.

Viscount GAGE, on behalf of Lord DESBOROUGH, introduced a Bill to enable the Council of the Pharmaceutical Society of Great Britain to make by-laws providing for the registration without examination of persons desiring to be registered as pharmaceutical chemists in Northern Ireland.

The Bill was read a first time.

HOUSE OF COMMONS.

WEDNESDAY, APRIL 17TH.

Small-pox on the s.s. "Tuscania."

Mr. JOHNSTON asked the Secretary of State for Scotland whether he was in a position to make any statement regarding the transfer of an engineer and of foodstuffs from the s.s. *Tuscania* to other ships at the port of Glasgow before the s.s. *Tuscania* was fumigated or disinfected after an outbreak of small-pox.—Sir J. GILMOUR replied: The s.s. *Tuscania* has been dealt with by the medical authorities of the Port of Glasgow in a manner authorised by the International Sanitary Convention of 1926, which was ratified by this country last year. Two engineers and some frozen fowls and frozen ducks were transferred from the *Tuscania* to the s.s. *Caledonia* before fumigation or disinfection had been carried out. The doctor and the purser of the *Caledonia* were notified that the engineers and foodstuffs were from the *Tuscania*. In terms of the International Sanitary Convention, the medical officer of health of Glasgow had no power to prevent the transfer to another vessel of the engineers, who were not suffering from small-pox, or of the foodstuffs, even if he had thought it desirable to do so. So far as is known, no other foodstuffs were transferred from the *Tuscania* to the *Caledonia* or any other ship. I am satisfied not only that the measures taken by the medical authorities of Glasgow are in accordance with the Convention, but also that they are all that could reasonably be done to prevent the spread of infection.

Vaccination Regulations at French Ports.

Mr. RAMSAY MACDONALD asked the Secretary of State for Foreign Affairs whether his attention had been drawn to the fact that all passengers from Great Britain, India, and certain other places were to be refused permission to land at French ports unless they could satisfy the French local medical officers of health that they had been vaccinated within the last two months; and whether he had any statement to make on the subject.—Sir AUSTEN CHAMBERLAIN replied: Immediately the new regulations were brought to their notice His Majesty's Government put themselves in communication with the French Government. I understand that the matter was considered this morning at a meeting of the Council of Ministers. Up to now I have received no official reply to the inquiries which I caused to be made, but the press this afternoon announce that at their meeting the Council of Ministers decided provisionally to suspend the Order and to arrange for a meeting between the French and English health authorities so that the two countries can act in common in taking whatever precautions may be deemed necessary. I am informed that the Southern Railway have issued a statement to the effect that vaccination certificates are not necessary for travellers to France.

THURSDAY, APRIL 18TH.

Sulphur Fumes from Electricity Plants.

Viscount SANDON asked the Minister of Transport whether he would immediately refer the question of the complete elimination of sulphur fumes from the workings of electricity generating plants to some body for scientific investigation and research; and whether, in the meantime, he would insist on sites for such purposes being chosen with full regard to the public interest, especially in the case of Battersea, in view of the effect of such fumes on the fabric of the Houses of Parliament.—Colonel W. ASHLEY replied: In approving sites for power stations regard is, of course, had to the public interest and opportunity is given for the hearing of any representations made, and no site in the County of London can be approved by the Electricity Commission without the consent of the Commissioners of Works unless the authority of Parliament has been obtained. When consent was given to the erection of the Battersea Power Station which is now under construction an obligation was placed upon the London Power Company to take the best known precautions for the due consumption of smoke, and for preventing, so far as reasonably practicable, the evolution of oxides of sulphur. I am assured by the Electricity Commissioners that in this modern power station effective steps can and will be taken to prevent the emission of grit and smoke. I am also informed that, with a view to compliance with their obligation, the company have been employing research chemists to work on the problem of the elimination of sulphur fumes, and have stated that satisfactory results have already been obtained in laboratory experiments. In view, however, of the public interests involved, the Electricity Commissioners, with my approval, have asked the Government chemist to examine these results and to keep in close touch with the progress of the company's investigation. In conjunction with the Department of Scientific and Industrial Research, he will advise the First Commissioner of Works and the Electricity Commissioners as to the efficiency of the measures proposed to be adopted to comply with the conditions on which consent has been given to the erection of the new station. The Ministers concerned with the various aspects of the question will remain in consultation with one another and watch it closely.

League of Nations and Radium Supplies.

Lieut.-Commander KENWORTHY asked the Prime Minister whether His Majesty's Government had under consideration proposals for international action through the League of Nations for the control of the available supplies of radium and their price; and, if not, whether any other proposals to this end were under consideration.—Mr. CHAMBERLAIN (Minister of Health) replied: As was stated in reply to Dr. Vernon Davies last Tuesday, the Government propose to establish an organisation, one of whose functions will be to act as an agency for the purchase of radium for medical use in this country or for Dominion or Colonial Governments. Until this organisation has been established and experience has shown how far it meets the needs of the situation, it would be premature to consider international action.

Lieut.-Commander KENWORTHY: As the question of international action is not dealt with in the Report, will the right hon. gentleman communicate with the Secretary of State for Foreign Affairs to see whether consultations can take place between the Governments concerned to prevent an unholy scramble for the available supply?

Mr. CHAMBERLAIN: I think it would be better to defer action on that point until we have this new organisation set up which I do not expect will take very long, and then perhaps we shall see.

Lieut.-Commander KENWORTHY: I do not cavil at what the right hon. gentleman says, but is he aware that the question of international action is not dealt with at all in the Report, and is that under the consideration of the Government?

Mr. CHAMBERLAIN: So far as I recollect, there is no question of international action mentioned in the Report of the Committee, but I think that the immediate question for this country is whether we can obtain the supplies that we require for ourselves at a reasonable price, and, as I understand, we have every reason to think that that can be done.

Dr. DAVIES: Can my right hon. friend say if we shall have a chance of discussing this Report before the House rises, particularly as the Government propose to spend pound for pound for the supply of this radium?

Mr. CHAMBERLAIN: There will have to be, I suppose, a Supplementary Estimate for the amount contributed by the Government, and I think that would give an opportunity for discussing the matter.

Replying to Mr. R. MORRISON, Mr. CHAMBERLAIN said that the Committee had now finished its labours.

Injurious Effects of Cream Preservatives.

Captain STREATFEILD asked the Minister of Health whether he had any evidence to show that illness or death had resulted from the use of preservatives in cream.—Mr. CHAMBERLAIN replied: There is evidence that individuals have suffered from digestive disorders after taking boracised cream, and there are cases on record where a single dose of borax has caused death. But, apart from the general objection to the use of preservatives in food as tending to mask the effects of dirty methods of production, the case against borax is that it is a cumulative and insidious chemical substance, the continued ingestion of which cannot fail to be injurious, in a greater or less degree, to the tissues of the body.

Hygienic Manufacture of Synthetic Cream.

Captain Streatfeild asked the Minister of Health whether his department had taken any steps to ensure that the manufacture of synthetic cream was carried out under the same conditions of hygiene as were imposed under the regulations governing the production of natural cream.—Mr. Chamberlain replied: I have not received any reports as to the conditions of manufacture of this article, but the provisions of Section 72 of the Public Health Act, 1925, should be sufficient to ensure the observance of all necessary sanitary precautions.

Mental Deficiency Committee's Report.

Lieut.-Commander Kenworthy asked the Minister of Health whether, having regard to the fact that local authorities would be submitting, as part of their schemes under the Local Government Act, their proposed arrangements for the care of mentally defective persons, he would take steps to see that the guidance which the report of the Joint Committee on Mental Deficiency would give to these local authorities should be made available for them without further delay.

Mr. Morris asked the Minister of Health whether he would state his decision in regard to the publication of that part of the report of the Special Committee on Mental Deficiency which related to adult defectives.

Mr. Robert Morrison asked the Minister of Health whether he was aware of the decision to publish the children's section of the report of the Mental Deficiency Committee; and, in view of the anxiety amongst those interested with regard to the section of the report dealing with adults, he would state the reason for the postponement of the decision to publish.—Mr. Chamberlain replied: I am not at present in a position to add anything to the previous replies in which I have indicated that I cannot give undertakings as to the publication of any part of this report other than that which relates to children until I have had an opportunity of giving proper consideration to the matter. I am afraid that other preoccupations have prevented that opportunity from occurring.

Mr. Morrison: In view of the fact that the conference of Poor-law Associations in connexion with this subject is to be held next week, will the right hon. gentleman consider the publication of the report, or at any rate the recommendations of the report.

Mr. Chamberlain: Clearly the recommendations are a vital part of the report. Until I have had an opportunity of considering this very long report, I cannot add anything to the answer I have given.

Mr. Pethick-Lawrence: Is it not a fact that the local authorities have to put part of this into force and to prepare schemes before September, and is it right that the right hon. gentleman should leave them so little time in which to have the report before them?

Mr. Chamberlain: There is a good deal of time between now and September, and I am not at all sure what effect on the liberty of the subject the report may have.

Mr. Morrison: Will the right hon. gentleman say definitely that the report will be published?

Mr. Chamberlain: No, I do not say that.

Dr. Vernon Davies: May we take it for granted that my right hon. friend will carefully study the report before arriving at a decision as to the schemes submitted by local authorities?

Mr. Chamberlain: Certainly.

Medical Officials on Local Authorities.

Sir Charles Trevelyan asked the Minister of Health whether, where the powers or duties of a board of guardians were transferred to a city or county council, a councillor who was holding a position such as that of doctor or public vaccinator under the transferred board would be compelled to resign his position as councillor if he was continued in his position under the new authority.—Mr. Chamberlain replied: I am advised that a person who, after April 1st, 1930, holds such a position as that of district medical officer or public vaccinator under a county or county borough council, will be disqualified from being a member of the council.

Dental Service in Welsh Schools.

Sir Robert Thomas asked the President of the Board of Education whether there were in Wales any entire counties or any other extensive areas, the education authorities of which provided no dental service in the schools; and, if so, whether he had any statistics of mortality, absenteeism, or other data showing how juvenile health in these counties compared with that prevailing in the counties which had a dental service.—Lord Eustace Percy replied: The three education authorities in Wales which at present make no provision for dental treatment are Cardiganshire, Carmarthen Borough, and Pembroke Borough. As regards the second part of the question, the hon. baronet will appreciate that the general health or mortality of school-children and their regularity of attendance at school are affected by a variety of causes, not readily separable.

Regulation of Nursing Homes.

Sir Robert Thomas asked the Minister of Health the number of private nursing homes in London, in the provinces, and in Wales, respectively; what were the regulations for the inspection and approval of these institutions by the local health authority prior to the admission of patients and subsequently; and how many inspections were carried out in each of the three groups mentioned above during the last 12 months to any convenient recent date.—Sir Kingsley Wood (Parliamentary Secretary to the Ministry of Health) replied: The Nursing Homes Registration Act, 1927, came into operation on July 1st, 1928. Medical officers of health have been asked to include statistics of homes registered under the Act in their annual reports for 1928, but these reports are not yet available. Premises within the scope of the Act are subject to the provisions of the Act and of by-laws made under it by local supervising authorities. These authorities are empowered to inspect nursing homes under Section 5 of the Act, but my right hon. friend has no detailed information as to their exercise of this power.

Small-pox on the s.s. "Tuscania."

Lieut.-Colonel Fremantle asked the Minister of Health the number of cases of small-pox that had occurred to date from the s.s. *Tuscania*; the number of these that had occurred since the official statement was issued on April 12th; the number that had died; the vaccination history of those who had died; whether any cases had occurred from contact with passengers or crew; and whether all passengers and crew were under observation and had been offered vaccination.—Mr. Chamberlain replied: The number of cases of small-pox which have occurred among the 1598 persons (passengers and crew) of the *Tuscania* is 45, which is ten more than the figure of 35 announced on April 13th. There have been seven deaths. The vaccination history of the patient who died, and of the other patients, is not yet available. All the patients notified have been isolated in hospital, and all the contacts are being kept under supervision. I have no information at present that any persons, other than those who were on board this ship, have contracted small-pox from contact with the passengers and crew. I am glad of this opportunity to say that the rigorous action which has been taken in this country to prevent the spread of small-pox from this vessel appears to have proved effectual. As the ship arrived here 17 days ago, any serious risk of a widespread outbreak of the disease should now be at an end, even though it is possible that some secondary cases may arise. It is scarcely necessary for me to add that for the community in general facilities are always available for free vaccination, which is the best safeguard against any risk of infection.

Lieut.-Colonel Fremantle asked whether the vaccination history of those who had died would be available in due course?

Mr. Chamberlain: Yes, Sir, I hope to be able to get it, and I will convey the information to my hon. and gallant friend.

Lieut.-Colonel Fremantle asked the Minister of Health the number of cases of small-pox that had occurred amongst passengers and crew of the s.s. *Mashobra*, shortly due at Southampton from Bombay; what number of passengers landed at Marseilles for England; and what steps were being taken to prevent the introduction of small-pox through them into this country.—Mr. Chamberlain replied: It is not yet known whether there has been any small-pox on board this vessel, but all precautions are being taken and she will be closely inspected at Plymouth, her first port of arrival. I am informed that 31 of her passengers were landed at Marseilles.

Small-pox in India.

Mr. Viant asked the Under Secretary of State for India what was the latest information in his possession in regard to the prevalence of small-pox in India.—Sir G. Hennessy, who replied, said: There is an epidemic of small-pox in Bombay City, where there were 233 cases and 130 deaths between Jan. 1st and Feb. 16th. There are no later official figures, but, according to a press report, the total number of deaths from Jan. 1st to March 18th was 368. In the whole of British India, between Jan. 1st and Feb. 16th, there were 19,529 cases and 4821 deaths, the case and mortality-rates being approximately the same as for 1928.

Vaccination and Visitors to France.

Lieut.-Colonel Fremantle asked the Secretary of State for Foreign Affairs if he had any information as to the requirements with regard to vaccination of visitors proceeding from this country to France; and what steps he was taking to help them conveniently to conform to these requirements.—Mr. LOCKER-LAMPSON (Under Secretary for Foreign Affairs) replied: Since my right hon. friend dealt with this matter yesterday official confirmation has been received of the suspension of the new French vaccination regulations. Discussions with the French Government are continuing.

Lieut.-Colonel FREMANTLE: Why is it that such action should have been taken when there are at least two international bodies that deal with health matters—one at Geneva and one at Paris?

The SPEAKER: That does not arise out of the right hon. gentleman's answer.

Poison Gas in War.

Mr. WILLIAM THORNE asked the Secretary of State for Foreign Affairs if he was aware that the German Reichstag had ratified the Geneva protocol prohibiting the use of poison gas in war; and whether the British Government had ratified the protocol.—Mr. LOCKER-LAMPSON replied: The proposal of the German Government to ratify the protocol was passed by the Reichstag on March 21st, but, so far as I am aware, Germany has not yet formally ratified. The answer to the second part of the question is in the negative.

MONDAY, APRIL 22ND.

Radium Supplies.

Mr. ROBERT MORRISON asked the Prime Minister when it was proposed to launch the public appeal for funds to purchase radium; and when the precise form of the organisation to be set up would be decided.—Sir KINGSLEY WOOD replied: The Government have no information as to the date of an appeal, though they hope it will be made in the near future. The precise form of the organisation recommended by the Radium Subcommittee, and accepted in principle by the Government, is already under discussion, and will, I hope, be settled in a very short time.

Mr. MORRISON asked whether the promised statement would be published before the General Election.

Sir KINGSLEY WOOD replied that he hoped it would be published within a few days.

Dr. VERNON DAVIES: Are we to understand that the Radium Trustees are already appointed and functioning?

No reply was given to this question.

Mr. MORRISON asked the Prime Minister whether the National Radium Trustees would have power to expend any of the funds in an endeavour to discover sources of supply independent of the Belgian company.—Sir KINGSLEY WOOD replied: No, Sir. The functions of the trustees as defined in paragraph 82 of the Radium Subcommittee's report will not extend to this purpose.

Insured Persons and Dental Treatment.

Mr. SHINWELL asked the Minister of Health whether he was aware that applicants for dental treatment who were members of approved societies in the London area were being inconvenienced through delays in dealing with their claims; and if he would inquire as to how far this was due to the methods employed by regional officers and take steps to expedite decisions in such cases.—Mr. CHAMBERLAIN replied: I am aware that owing to a large and rapid increase in the number of cases referred to the regional dental staff there have been some delays of the kind suggested. Steps have been taken to deal with the position, and a considerable improvement has already been effected, the clearance of references in London itself being now up to date.

Fumes from Artificial Silk Works.

Dr. VERNON DAVIES asked the Minister of Health whether he had received any reports from his inspectors regarding the emission of fumes from artificial silk works.—Sir KINGSLEY WOOD replied: Yes, Sir. The chief alkali inspector has made a report on this subject and my right hon. friend is arranging for its publication.

TUESDAY, APRIL 23RD.

Night Telephone Calls for Medical Men.

Mr. HORE-BELISHA asked the Postmaster-General whether his attention had been called to a coroner's criticism at a Surrey inquest of the telephone service, in which he stated that it was not the first case that had come before him where an urgent summons had been sent through to the telephone exchange during the night and no reply had been received; and what steps he intended to take to render the night telephone service efficient.

Mr. ROBERT MORRISON asked the Postmaster-General whether he had held an inquiry into the alleged failure of the night telephone service to which attention was drawn at a recent inquest at Croydon; and what was the result.

Sir ROBERT THOMAS asked the Postmaster-General whether he was aware that the father of a young man taken ill recently in the early hours of the morning attempted to telephone for a doctor, but failed to get a reply from the exchange although he tried for three-quarters of an hour; that the coroner subsequently stated that this was not the first case in his experience when the exchange made no reply to an urgent night summons; and whether he would make a general statement on the question of night staffs for telephone exchanges.—Sir W. MITCHELL-THOMSON replied: I have made full inquiry into this case, and greatly regret to find that there was a failure of the night telephone service on this occasion. It has not been possible to determine the precise cause of the failure, and I can find no record of a similar case in the same locality. A system of periodical testing has been for some time in force at night telephone exchanges, and the latest records show that the average speed of answer by the operators is satisfactory. I propose to extend this testing system further, and am at present considering the best means of so doing.

Mr. HORE-BELISHA asked if the Postmaster-General was not aware that there had been very considerable and almost universal dissatisfaction with this service for a long time, and if his attention had been called to the specific complaint made by doctors, notably by the hon. secretary of the blood transfusion section of the Red Cross Society, in which allegations had been made about loss of life owing to the delays in this service; and if he was doing anything to expedite inquiries?

Sir W. MITCHELL-THOMSON: I cannot say that I have an accurate recollection of that particular complaint, but I am aware of the fact that there have been complaints. That is the reason why these tests were made. The tests showed that the average speed of answers, taken all round, was not unsatisfactory.

First-aid Appliances at Collieries.

Mr. THOMAS WILLIAMS asked the Secretary for Mines when the new regulations relating to first-aid appliances, &c., at collieries were issued; and what steps his inspectors were taking to see that such regulations were being adhered to.—Commodore H. DOUGLAS KING replied: The first-aid regulations at present in force are those of July 10th, 1913, and their observance is checked by inspections at all the collieries. The proposed new regulations on this subject are being discussed with representative bodies of the industry, and have not yet been issued.

Mortality from Influenza.

Mr. MALONE asked the Minister of Health whether his attention had been drawn to the returns of the Registrar-General showing that in the first quarter of this year the deaths recorded exceeded the births by 24,105, the deaths for the most part being due to the influenza epidemic; whether he was aware that in the Midlands in the first week of March the death-rate from influenza alone, not including derivative diseases, reached the figure of 0·67 per 1000; and whether any research into this disease had been undertaken by the Medical Research Council during the past year or was being undertaken or contemplated by the Council at the present time.—Sir KINGSLEY WOOD replied: The returns issued by the Registrar-General show that in the first quarter of this year the deaths in 107 great towns in England and Wales exceeded the births by 25,108. The deaths numbered 111,003, influenza being certified as one of the causes of death in 12,711 cases. No similar figures are yet available for the country as a whole. The death-rate from influenza quoted in the second part of the question relates only to the great towns in the Midlands. As regards the last part of the question, I am informed that the Medical Research Council are actively promoting researches into the group of diseases to which influenza is believed to belong.

International Action in Health Measures.

Sir WALTER DE FRECE asked the Minister of Health whether there existed any international machinery, and, if so, of what nature, to enable the fullest prior exchange of views between the health authorities of different countries before, by any one country, a health or sanitary ordinance was issued against the subjects of another.—Sir KINGSLEY WOOD replied: The International Sanitary Convention of 1926 defines the measures that may be taken by countries which are parties to the Convention in order to prevent the introduction and spread of certain communicable diseases. The Convention does not require that there shall be an exchange of views between the countries concerned before the restrictions authorised by the Convention are imposed.

EVELINA HOSPITAL, SOUTHWARK.—An anonymous donor has promised to build and equip a convalescent home if the hospital can collect an endowment fund within three years. As soon as £10,000 is in hand the building will be begun.

objection to the use of preservatives in food as tending to mask the effects of dirty methods of production, the case against borax is that it is a cumulative and insidious chemical substance, the continued ingestion of which cannot fail to be injurious, in a greater or less degree, to the tissues of the body.

Hygienic Manufacture of Synthetic Cream.

Captain STREATFEILD asked the Minister of Health whether his department had taken any steps to ensure that the manufacture of synthetic cream was carried out under the same conditions of hygiene as were imposed under the regulations governing the production of natural cream.—Mr. CHAMBERLAIN replied : I have not received any reports as to the conditions of manufacture of this article, but the provisions of Section 72 of the Public Health Act, 1925, should be sufficient to ensure the observance of all necessary sanitary precautions.

Mental Deficiency Committee's Report.

Lieut.-Commander KENWORTHY asked the Minister of Health whether, having regard to the fact that local authorities would be submitting, as part of their schemes under the Local Government Act, their proposed arrangements for the care of mentally defective persons, he would take steps to see that the guidance which the report of the Joint Committee on Mental Deficiency would give to these local authorities should be made available for them without further delay.

Mr. MORRIS asked the Minister of Health whether he would state his decision in regard to the publication of that part of the report of the Special Committee on Mental Deficiency which related to adult defectives.

Mr. ROBERT MORRISON asked the Minister of Health whether he was aware of the decision to publish the children's section of the report of the Mental Deficiency Committee; and, in view of the anxiety amongst those interested with regard to the section of the report dealing with adults, he would state the reason for the postponement of the decision to publish.—Mr. CHAMBERLAIN replied : I am not at present in a position to add anything to the previous replies in which I have indicated that I cannot give undertakings as to the publication of any part of this report other than that which relates to children until I have had an opportunity of giving proper consideration to the matter. I am afraid that other preoccupations have prevented that opportunity from occurring.

Mr. MORRISON : In view of the fact that the conference of Poor-law Associations in connexion with this subject is to be held next week, will the right hon. gentleman consider the publication of the report, or at any rate the recommendations of the report.

Mr. CHAMBERLAIN : Clearly the recommendations are a vital part of the report. Until I have had an opportunity of considering this very long report, I cannot add anything to the answer I have given.

Mr. PETHICK-LAWRENCE : Is it not a fact that the local authorities have to put part of this into force and to prepare schemes before September, and is it right that the right hon. gentleman should leave them so little time in which to have the report before them ?

Mr. CHAMBERLAIN : There is a good deal of time between now and September, and I am not at all sure what effect on the liberty of the subject the report may have.

Mr. MORRISON : Will the right hon. gentleman say definitely that the report will be published ?

Mr. CHAMBERLAIN : No, I do not say that.

Dr. VERNON DAVIES : May we take it for granted that my right hon. friend will carefully study the report before arriving at a decision as to the schemes submitted by local authorities ?

Mr. CHAMBERLAIN : Certainly.

Medical Officials on Local Authorities.

Sir CHARLES TREVELYAN asked the Minister of Health whether, where the powers or duties of a board of guardians were transferred to a city or county council, a councillor who was holding a position such as that of doctor or public vaccinator under the transferred board would be compelled to resign his position as councillor if he was continued in his position under the new authority.—Mr. CHAMBERLAIN replied : I am advised that a person who, after April 1st, 1930, holds such a position as that of district medical officer or public vaccinator under a county or county borough council, will be disqualified from being a member of the council.

Dental Service in Welsh Schools.

Sir ROBERT THOMAS asked the President of the Board of Education whether there were in Wales any entire counties or any other extensive areas, the education authorities of which provided no dental service in the schools ; and, if so, whether he had any statistics of mortality, absenteeism, or other data showing how juvenile health in these counties compared with that prevailing in the counties which had a dental service.—Lord EUSTACE PERCY replied : The three education authorities in Wales which at present make no provision for dental treatment are Cardiganshire, Carmarthen Borough, and Pembroke Borough. As regards the second part of the question, the hon. baronet will appreciate that the general health or mortality of school-children and their regularity of attendance at school are affected by a variety of causes, not readily separable.

Regulation of Nursing Homes.

Sir ROBERT THOMAS asked the Minister of Health the number of private nursing homes in London, in the provinces, and in Wales, respectively ; what were the regulations for the inspection and approval of these institutions by the local health authority prior to the admission of patients and subsequently ; and how many inspections were carried out in each of the three groups mentioned above during the last 12 months to any convenient recent date.—Sir KINGSLEY WOOD (Parliamentary Secretary to the Ministry of Health) replied : The Nursing Homes Registration Act, 1927, came into operation on July 1st, 1928. Medical officers of health have been asked to include statistics of homes registered under the Act in their annual reports for 1928, but these reports are not yet available. Premises within the scope of the Act are subject to the provisions of the Act and of by-laws made under it by local supervising authorities. These authorities are empowered to inspect nursing homes under Section 5 of the Act, but my right hon. friend has no detailed information as to their exercise of this power.

Small-pox on the s.s. "Tuscania."

Lieut.-Colonel FREMANTLE asked the Minister of Health the number of cases of small-pox that had occurred to date from the s.s. *Tuscania* ; the number of these that had occurred since the official statement was issued on April 12th ; the number that had died ; the vaccination history of those who had died ; whether any cases had occurred from contact with passengers or crew ; and whether all passengers and crew were under observation and had been offered vaccination.—Mr. CHAMBERLAIN replied : The number of cases of small-pox which have occurred among the 1598 persons (passengers and crew) of the *Tuscania* is 45, which is ten more than the figure of 35 announced on April 13th. There have been seven deaths. The vaccination history of the patient who died, and of the other patients, is not yet available. All the patients notified have been isolated in hospital, and all the contacts are being kept under supervision. I have no information at present that any persons, other than those who were on board this ship, have contracted small-pox from contact with the passengers and crew. I am glad of this opportunity to say that the rigorous action which has been taken in this country to prevent the spread of small-pox from this vessel appears to have proved effectual. As the ship arrived here 17 days ago, any serious risk of a widespread outbreak of the disease should now be at an end, even though it is possible that some secondary cases may arise. It is scarcely necessary for me to add that for the community in general facilities are always available for free vaccination, which is the best safeguard against any risk of infection.

Lieut.-Colonel FREMANTLE asked whether the vaccination history of those who had died would be available in due course ?

Mr. CHAMBERLAIN : Yes, Sir, I hope to be able to get it, and I will convey the information to my hon. and gallant friend.

Lieut.-Colonel FREMANTLE asked the Minister of Health the number of cases of small-pox that had occurred amongst passengers and crew of the s.s. *Mashobra*, shortly due at Southampton from Bombay ; what number of passengers landed at Marseilles for England ; and what steps were being taken to prevent the introduction of small-pox through them into this country.—Mr. CHAMBERLAIN replied : It is not yet known whether there has been any small-pox on board this vessel, but all precautions are being taken and she will be closely inspected at Plymouth, her first port of arrival. I am informed that 31 of her passengers were landed at Marseilles.

Small-pox in India.

Mr. VIANT asked the Under Secretary of State for India what was the latest information in his possession in regard to the prevalence of small-pox in India.—Sir G. HENNESSY, who replied, said : There is an epidemic of small-pox in Bombay City, where there were 233 cases and 130 deaths between Jan. 1st and Feb. 16th. There are no later official figures, but, according to a press report, the total number of deaths from Jan. 1st to March 18th was 368. In the whole of British India, between Jan. 1st and Feb. 16th, there were 19,529 cases and 4821 deaths, the case and mortality-rates being approximately the same as for 1928.

Vaccination and Visitors to France.

Lieut.-Colonel FREMANTLE asked the Secretary of State for Foreign Affairs if he had any information as to the

Mr. Paul Bernard Roth has resigned his post as orthopædic surgeon to the London Homœopathic Hospital, while retaining his appointments elsewhere.

MANCHESTER AND DISTRICT RADIUM INSTITUTE.—During the past year this Institute's beds have been kept fully occupied, though owing to the greater length of the treatment the number of in-patients was only 374, as compared with 560 in 1927. The number of out-patients has risen to 7438, and there has been a marked increase in the demand for the radium treatment of cancer. The waiting-list has grown steadily, and treatment has had to be refused to many would-be patients. Dr. G. E. Birkett, honorary radiologist to the Institute, says in the annual report that concentration is being directed to the treatment of, and results of, carcinoma of the mouth and tongue. So far, during the last three years 250 cases of this type have been treated. Unless more radium is available, however, *further advances will not be made. Limited facilities are* the reason why so few cases of carcinoma of the breast have been dealt with. At the annual meeting on April 11th it was stated that, provided certain difficulties were overcome, in all probability there would in the near future be an amalgamation of the Institute with the Cancer Hospital, with a new hospital on a convenient site, complete with every modern convenience, and with a special annexe for the storage of radium and research work.

ROYAL MEDICAL BENEVOLENT FUND.—Sir Thomas Barlow, F.R.S., the President, took the chair at the ninety-third annual meeting of this Fund on April 18th. It was reported that the past year had been very successful, the number of new subscribers testifying to an awakened interest among members of the profession. The subscriptions and donations totalled £8623, compared with £7590 in 1927, the sum of £1667 being received as a result of the coöperation of the British Medical Association. Despite the increased income, however, the committee regrets that the amount of the grants made was often insufficient to meet the needs of the cases relieved. Thus the maximum annual grant that could be made to an entirely destitute widow was only £36, and appeals had often to be made to other charities to coöperate with the Fund in helping dependants of medical practitioners. Increased subscriptions and new subscribers were therefore needed, and for various reasons it would be a help to the Fund if subscribers would send their contributions during the first quarter of the year rather than later. The number of grants made in 1928 was 485, amounting to £8772, and many of the cases were very distressing. About £500 was spent on the education of orphans. A fair response was received to the appeal for contributions towards children's summer holidays, and 333 Christmas gifts were made, amounting in all to £500, together with £100 for coal. The sum paid in annuities was £4813, and owing to a legacy it had been possible to give six Alexander Lawrence annuities of £100 each. The number of annuitants of the Fund was 179. Among legacies received during the year was one of £5000 from the late Prof. Thelwall Thomas.

The officers of the Society elected for the coming year included Sir Thomas Barlow, President; Sir Charters Symonds, hon. treasurer; and Sir Percy Sargent and Mr. R. M. Handfield-Jones, hon. secretaries.

Medical Diary.

SOCIETIES.

ROYAL SOCIETY, Burlington House, Piccadilly, W.

Marshall and J. Hammond: Œstrus and Pseudo-Pregnancy in the Ferret. R. G. Canti and F. G. Spear: The Effect of Gamma Irradiation on Cell Division in Tissue Culture in vitro. (Communicated by Sir Frederick Andrewes. R. B. Bourdillon, C. Fischmann, R. G. C. Jenkins, and T. A. Webster: The Absorption Spectrum of Vitamin D. (Communicated by Dr. H. H. Dale.)—*The following papers will be read in title only:* G. E. Briggs: Experimental Researches on Vegetable Assimilation and Respiration. XX. (Communicated by F. F. Blackman.) R. J. Lythgoe and K. Tansley: The Relation of the Critical Frequency of Flicker to the Adaptation of the Eye. (Communicated by Sir John Parsons.) R. Hill: Reduced Hæmatin and Hæmochromogen. (Communicated by Sir Frederick Hopkins.)

ROYAL SOCIETY OF MEDICINE, 1, Wimpole-street, W.

WEDNESDAY, May 1st.—5 P.M., HISTORY OF MEDICINE: Annual General Meeting. Election of Officers and Council. Exhibit: Statuette of Imhotep, an ancient Egyptian deity of medicine, and a rare scarab associated with him: lent for exhibition by Dr. Hurry. Paper: Sir William Hale-White: The Letters of Dr. William Withering. 8.30 P.M., SURGERY. Annual General Meeting: Election of Officers and Council. SURGERY and MEDICINE to follow the Annual Meeting of the Section of Surgery. Discussion on the Indications for and the Results of Splenectomy. Openers: Mr. A. J. Walton (Surgery); and Dr. Hugh Thursfield (Medicine).

FRIDAY.—10.30 A.M., OTOLOGY. (Cases at 9.30 A.M.). Annual General Meeting: Election of Officers and Council. Subject for Discussion: The Treatment of Chronic Deafness. Short Papers: Dr. Dan McKenzie: The Symptomatic Treatment of Deafness. Mr. Harold Kisch: Chronic Deafness: its Treatment and Prevention. Mr. Thacker Neville: Chronic Deafness. Mr. G. Seccombe Hett and Mr. A. G. Wells: Ionisation as a Treatment for Middle-ear Suppuration. Cases and Specimens will be shown by Mr. Somerville Hastings, Mr. E. Watson-Williams, and others. 5 P.M., LARYNGOLOGY: (Cases at 4 P.M.). Annual General Meeting: Election of Officers and Council. Paper: Mr. F. J. Cleminson: Treatment of *Carcinoma of the* Œsophagus by Radium. Cases and Specimens will be shown by Mr. Somerville Hastings, Dr. D. R. Paterson, Mr. M. Vlasto Mr Frank Rose, Dr. P. Watson-Williams, and Mr. A. J. Wright. 8.30 P.M., ANÆSTHETICS. Annual General Meeting: Election of Officers and Council. Short Paper: Dr. H. Sington: Pre-medication by Paraldehyde in Children.

MEDICAL SOCIETY FOR THE STUDY OF VENEREAL DISEASES, 11, Chandos-street, Cavendish-square, W.

FRIDAY, May 3rd.—8.30 P.M., Mr. Frank Kidd: Vasostomy and its Place in the Treatment of Early Urethritis. A Discussion will follow.

LECTURES, ADDRESSES, DEMONSTRATIONS, &c.

ROYAL COLLEGE OF PHYSICIANS, Pall Mall East, S.W.

TUESDAY, April 30th.—5 P.M., Dr. F. M. R. Walshe: The Physiological Analysis of Some Clinically Observed *Disorders of Movement. (First Oliver-Sharpey Lecture).*

THURSDAY, May 2nd.—5 P.M. (Second Oliver-Sharpey Lecture).

FELLOWSHIP OF MEDICINE AND POST-GRADUATE MEDICAL ASSOCIATION, 1, Wimpole-street, W.

MONDAY, April 29th, to SATURDAY, May 5th.—CITY OF LONDON HOSPITAL FOR DISEASES OF THE HEART AND LUNGS, Victoria Park, E. Tues., at 2 P.M., Dr. H. V. Morlock: The Early Infiltration and its Relation to the Development of Phthisis.—HAMPSTEAD GENERAL HOSPITAL, Haverstock Hill, N.W. Tues., 2.15 P.M., Mr. George Waugh (Wards).—The above are free.—LONDON SCHOOL OF HYGIENE AND TROPICAL MEDICINE, Endsleigh-gardens, W.C. Tues. and Thurs., 2 P.M., Lecture-demonstration.—ROYAL WATERLOO HOSPITAL, Waterloo-road, S.E., Special Course in Medicine, Surgery and Gynæcology.—ROYAL FREE HOSPITAL, Gray's Inn-road, W.C., Wed., Demonstration on Electrotherapeutic Methods and Apparatus.—WEST END HOSPITAL FOR NERVOUS DISEASES, 73, Welbeck-street, W.—Daily Lecture-demonstrations illustrated by cases at 5 P.M.—MAUDSLEY HOSPITAL, Denmark Hill, S.E., Four weeks special course in Psychological Medicine.—CENTRAL LONDON THROAT, NOSE AND EAR HOSPITAL, Gray's Inn road, W.C., Intensive Course.—Further particulars from the Fellowship of Medicine.

WEST LONDON HOSPITAL POST-GRADUATE COLLEGE, Hammersmith, W.

MONDAY, April 29th.—10 A.M., Dr. Dowling: Skin Department. 2 P.M., Mr. Donald Armour: Operations. 2 P.M., Dr. Ironside: Medical Out-patients.

TUESDAY.—10 A.M., Medical Registrar: Ward Visit. 2 P.M., Mr. Addison, Operations. 2 P.M., Mr. Sinclair: Surgical Out-patients.

WEDNESDAY, May 1st.—10 A.M., Dr. Owen: Children's Out-patient Department. 2 P.M., Mr. Tyrrell Gray: Operations. 2 P.M., Dr. Scott Pinchin: Medical Out-patients.

THURSDAY.—10 A.M., Dr. Grainger Stewart: Neurological Department. 11.30 A.M., Mr. Simmonds: Demonstration of Fractures. 2 P.M., Mr. MacDonald: Genito-Urinary Out-patient Department.

FRIDAY.—10 A.M., Dr. Pritchard: Medical Ward Visit. 12 noon, Dr. Shaw: Clinical Demonstration. 2 P.M., Mr. Vlasto: Throat, Nose and Ear Department.

SATURDAY.—9.30 A.M., Dr. Burnford: Bacterial Therapy Department. 10 A.M., Dr. Owen: Children's Medical Out-patient Department. 10 A.M., Resident Assistant Surgeon: Ward Visit. Medical and Surgical Out-patients at 2 P.M., daily. Operations. Special Departments daily 10 A.M., to 5 P.M., Saturdays, 10 A.M. to 1 P.M. Special Classes in Anæsthetics and Operative Surgery.

NORTH-EAST LONDON POST-GRADUATE COLLEGE, Prince of Wales's General Hospital, Tottenham, N.

MONDAY, April 29th.—2.30 to 5 P.M.: Medical, Surgical, and *Gynæcological Clinics. Operations.*

TUESDAY.—2.30 to 5 P.M.: Medical, Surgical, Throat, Nose and Ear Clinics. Operations.

WEDNESDAY.—2.30 to 5 P.M.: Medical, Skin, and Eye Clinics. Operations.

THURSDAY.—11.30 A.M.: Dental Clinics. 2.30 to 5 P.M.: Medical, Surgical, Nose, Throat and Ear Clinics. Operations.

FRIDAY.—10.30 A.M.: Throat, Nose and Ear Clinics. 2.30 to 5 P.M., Surgical, Medical, and Children's Diseases Clinics. Operations.

UNIVERSITY COLLEGE, Gower-street, London.

MONDAY, April 29th, and the following TUESDAY and WEDNESDAY.—5.15 P.M., Prof. E. Mellanby: Drug-like Actions of Some Food Constituents. (Public Lectures).

THURSDAY, May 2nd.—5 P.M., Mr. R. J. Lythgoe: Special Sense Physiology. (First of six lectures.)

FRIDAY.—4 P.M., Prof. A. J. Hall: Some of the Sequels of Epidemic Encephalitis (Lethargica). (First of two public lectures.)

ST. THOMAS'S HOSPITAL, Albert Embankment, Westminster Bridge, S.E.

THURSDAY, May 2nd.—5 P.M., Prof. S. J. Cowell: Dietetics. (First of six lectures.)

ROYAL NORTHERN HOSPITAL, Holloway-road, N.

WEDNESDAY, May 1st.—3.15 P.M., (at the Royal Chest Hospital, City-road), Dr. F. E. Saxby Willis: Thoracic Pain.

ROYAL DENTAL HOSPITAL POST-GRADUATE LECTURES.

WEDNESDAY, May 1st.—6 P.M., Dr. E. W. Fish: The Reaction of the Pulp and Dentine to Dental Caries.

LONDON SCHOOL OF DERMATOLOGY, St. John's Hospital, 49, Leicester-square, W.C.

THURSDAY, May 2nd.—5 P.M., Dr. A. M. H. Gray: The Sacroids and Lupus Pernio.

FRIDAY.—5 P.M., Dr. A. C. Roxburgh: Differential Diagnosis of Some Common Skin Diseases.

MANCHESTER ROYAL INFIRMARY POST-GRADUATE COURSE.

TUESDAY, April 30th.—4.15 P.M., Mr. J. Morley: The Pain Associated with Gall-stones.

FRIDAY, May 3rd.—4.15 P.M., Dr. E. B. Leech: Demonstration of Medical Cases.

ANCOATS HOSPITAL POST-GRADUATE LECTURES, Mill-street, Manchester.

THURSDAY, May 2nd.—4.15 P.M., Mr. E. E. Hughes: Pyelitis.

Appointments.

DUNSCOMBE, N. D., M.B., B.Chir. Camb., D.P.H., has been appointed Medical Officer of Health, Bexhill.

FERGUSON, J., M.B., B.Ch. R.U.I., D.P.H., County Medical Officer of Health for Surrey.

Certifying Surgeons under the Factory and Workshop Acts: ANDERSON, H. P., M.B., Ch.B. Edin. (Kinross); SUTHERLAND, T. R., L.R.C.P. Lond., M.R.C.S. (Tredegar); TULLIS, G. D. E., M.B., Ch.B. Edin. (Hereford); and WHITBY, J. M. F., L.M.S.S.A. Lond. (Littleport, Cambs.)

Vacancies.

For further information refer to the advertisement columns.

Ashton-under-Lyne, District Infirmary.—H.S. At rate of £150.

Bedford County Hospital.—Asst. H.S. At rate of £130.

Bedfordshire Sanatorium, near Bedford.—Res. Asst. M.O. £450.

Birkenhead County Borough.—Asst. M.O. £450.

Birmingham, City Mental Hospital.—Jun. Asst. M.O. £350.

Birmingham and Midland Eye Hospital, Church-street.—Surgical Registrar.

Blackburn and East Lancashire Royal Infirmary.—4th H.S. At rate of £130.

Bolingbroke Hospital, Wandsworth Common, S.W.—Clin. Asst. to Ear, Nose and Throat Dept. £75.

Brighton, Royal Sussex County Hospital.—Cas. H.S. £120.

Brighton, Sussex Eye Hospital.—Hon. Consulting Physician and Neurologist. Hon. Consulting Rhinologist. Also Hon. Consulting Dentist.

Bristol Education Committee.—Asst. School M.O. £600.

Bristol Royal Infirmary.—Hon. Med. Reg. Also Hon. Reg. to Ear, Nose and Throat Dept.

Bristol University.—Chair of Physiology.

Cancer Hospital, Fulham-road, S.W.—H.S. At rate of £100.

Canterbury, Kent and Canterbury Hospital.—Two Res. M.O.'s Each £125.

Cardiff, King Edward VII. Welsh National Memorial Association.—Area Asst. Tuber. Physician. £600.

Central London Throat, Nose and Ear Hospital, Gray's Inn-road, W.C.—Second Res. H.S. £75.

City of London Maternity Hospital, City-road, E.C.—Asst. Obstetric Surgeon.

Colchester, Essex County Hospital.—Asst. H.S. and Registrar. £120.

Derby Guardians' Institution and Infirmary.—Second Res. M.O. £250.

East Ham County Borough.—Asst. M.O. £600.

East London Hospital for Children, &c., Shadwell, E.—Res. H.S. Also Res. Cas. O. Each at rate of £125.

Edinburgh Royal Infirmary.—Hon. Clinical Assistants.

Folkestone, Borough of.—Asst. M.O.H. £600.

Glasgow, Victoria Infirmary.—Superintendent. £1000.

Guildford, Royal Surrey County Hospital.—H.S. At rate of £150.

Hospital of St. John and St. Elizabeth, 60, Grove End-road, N.W.—Res. H.P. At rate of £100.

Hull Royal Infirmary.—Cas. H.S. At rate of £130.

Kingston-upon-Hull City and County of.—Asst. M.O.H. £600.

Leeds Public Dispensary.—Sen. Res. M.O. £200.

Leeds, Tuberculosis Sanatorium, Killingbeck.—Asst. Res. M.O. £250.

Liverpool Port Sanitary Authority.—Asst. Port M.O. £700.

London Hospital, Whitechapel, E.—Gynæcological First Asst. and Obstetric Tutor. £300.

London Female Lock Hospital, Harrow-road, W.—Hon. Obstet. Surg.

London Homœopathic Hospital, Great Ormond-street, and Queen-square, Bloomsbury, W.C.—Res. M.O. £100.

London Temperance Hospital, Hampstead-road, N.W.—Surg. Reg. 40 guineas.

Manchester Royal Infirmary.—First Asst. in Clinical Laboratory £350. Also Dickinson Research Travelling Scholarship in Medicine. £300. Also Pathology Scholarship. £75.

New End Hospital, Hampstead, N.W.—Jun. Res. Asst. M.O. At rate of £200.

Norwich City Mental Hospital.—Jun. Asst. M.O. £500.

Norwich, Norfolk and Norwich Hospital.—H.P. Also Cas. O and H.S. Each £120.

Nottingham General Hospital.—Res. Cas. O. At rate of £200.

Plumstead and District Hospital, Plumstead High-street, S.E.—Third Asst. M.O. £300.

Royal Army Medical College, Grosvenor-road, S.W.—Parkes Memorial Prize. £75. Also Alexander Memorial Prize. £50.

Royal Chest Hospital, City-road, E.C.—Res. M.O. At rate of £150. Also H.P. At rate of £100.

Royal Eye Hospital, St. George's-circus, Southwark, S.E.—H.S. Also Asst. H.S. At rate of £150 and £100 respectively.

Royal Free Hospital, Gray's Inn-road, W.C.—Asst. Morbid Anatomist and Curator of Museum. £300.

Royal London Ophthalmic Hospital, City-road, E.C.—Out-patient Officer. £100.

Royal National Orthopædic Hospital, 234, Great Portland-street, W. Surgical Registrar. At rate of £105.

St. Bartholomew's Medical College.—Senior Curator of Museum.

St. Helens County Borough.—Asst. M.O.H. £450.

St. John's Hospital, Lewisham, S.E.—Sen. Res. M.O. £250.

Samaritan Free Hospital for Women, Marylebone-road, N.W.—H.S. At rate of £100.

University of London.—University Chair of Anatomy. £1000.

Wakefield, Clayton Hospital.—H.S. £150.

Walsall General Hospital.—Jun. H.S. At rate of £100. Also H.S. At rate of £125.

Wolverhampton, Royal Hospital.—Res. M.O. At rate of £150.

Wolverhampton and Midland Counties Eye Infirmary.—H.S. £200.

Woolwich and District War Memorial Hospital, Shooters' Hill, S.E.—H.S. At rate of £125.

The Chief Inspector of Factories announces vacant appointments for Certifying Factory Surgeons at Tipton (Staffs), and Leeds North (Yorks.).

Births, Marriages, and Deaths.

BIRTHS.

GARROW.—On April 19th, at Fernbrae, Dundee, the wife of Dr. R. P. Garrow, Great North-road, Highgate, N., of a son.

HORDER.—On April 20th, at Ben-Lui, Boyne-park, Tunbridge Wells, the wife of Cecil A. Horder, M.B., F.R.C.S., of a son.

NEWNHAM.—On April 17th, at a nursing home, Crayford, Kent, the wife of Dr. F. M. Newnham, of a son.

PAYNE.—On April 16th, the wife of Reginald T. Payne, F.R.C.S., of Abbey Court, St. John's Wood, of a son.

SELOUS.—On April 16th, at Tunbridge Wells, the wife of Cuthbert F. Selous, M.B., of a son.

TINCKER.—On April 17th, at Painswick, Glos., the wife of Surgeon-Lieutenant R. W. Holden Tincker, R.N.V.R., of a daughter.

MARRIAGES.

HOLLINS—STADDON.—On April 16th, at St. John's Church, Ipswich, Arthur Sturgess Hollins, B.A., M.R.C.P., of Thames Ditton, to Joan Staddon, M.R.C.S., of Ipswich.

SUMMERS—BATES.—On April 16th, at SS. Nicholas and Faith Church, Saltash, Ralph Donald Summers, L.R.C.P., M.R.C.S., to Florence Mathilde, daughter of Mr. and Mrs. W. Bates, of Port View, Saltash.

DEATHS.

AHRENS.—On April 16th, Henry Augustus Ahrens, M.R.C.S., L.R.C.P., late Surgeon-Major, Hants Carabineers, of Grangethorpe Hospital, Manchester, aged 59 years.

BRADNACK.—On April 21st, 1929, Gerald A. A. Bradnack, M.R.C.S., L.R.C.P., beloved husband of Nora Winifred Bradnack, M.B., B.S. (née Kirk). At Barton-on-Humber. Aged 33.

CAPON.—On April 20th, the beloved wife for 50 years of Herbert J. Capon, M.D., at Pine View, Sonning Common, Reading.

DAWES.—On April 18th, Joseph William Dawes, M.B., C.M., of Denbigh House, Longton, aged 65 years.

FARRAR.—On April 17th, at Hillmorton Paddox, Rugby, John Frederick Farrar, M.R.C.S. Eng., L.R.C.P. Lond., late of Putney, aged 74.

LAWRENCE.—On April 15th, at Hoath Cottage, Hadlow, Kent, Dr. H. M. Lawrence, aged 84.

RUTHERFURD.—At 20, Bute-gardens, Glasgow, W.2, on 14th April, 1929, Henry Rutherfurd, M.A., M.B., C.M., F.R.F.P.S.G.

SCHOFIELD.—On April 20th, at Bursleden Hotel, East Cliff, Bournemouth, Alfred Taylor Schofield, M.D., M.R.C.S., late of Harley-street, in his 83rd year.

N.B.—A fee of 7s. 6d. is charged for the insertion of Notices of Births, Marriages, and Deaths.

Notes, Comments, and Abstracts.

SMALL-POX DIAGNOSIS.

BY W. MCCONNEL WANKLYN, B.A. CAMB.,
M.R.C.S. ENG., D.P.H.

WHEN by the Act of 1898 Parliament in its wisdom virtually *made vaccination optional, and confirmed that* measure by the Act of 1907, the people of this country in effect elected to discontinue protecting themselves against small-pox by the method of each member of the community rendering himself individually immune. Without realising it, they decided to substitute another method of protection—namely, the formation of an elaborate and efficient organisation for the purpose in the first place of instantly recognising small-pox, and then of rapidly suppressing it. *The cutting edge of this organisation is the accurate diagnosis of small-pox, which the administrative measures follow.* It is clear that everything turns on the sharpness of this cutting edge.

A Certain Means of Recognising Small-pox.

Happily for the country, before its renunciation of general vaccination, material for the new method of protection had been *in preparation owing to the work of the late Dr. T. F. Ricketts, which began in 1891. During this decade he* forged against small-pox a weapon happily described by himself as "the brand Excalibur"; it was a rapid and certain *means of recognising small-pox*, with the outstanding merit that it was readily capable of being communicated to others. Although finished skill in the use of this, as of any other weapon, can only come from natural talent or long training, it is a fact that by its use cases of small-pox have *even* been recognised on the first day of the rash by members of the medical profession who had never previously seen a case of the disease. It is something for which humanity may be thankful that one of the worst of infectious plagues betrays *itself early by a characteristic skin eruption* which it is not—*to use the phrasing of the National Insurance Act*—beyond the ability of the practitioner of ordinary competence and skill to discover.

Tested on a large scale in 1902, the method of Ricketts enabled all but two of 8000 cases certified as small-pox to be correctly classified: of cases so examined, about 600 were pronounced to be not small-pox *and 7400 to be* small-pox. This was done rapidly and at high pressure, by members of a team, several of whom had had no previous knowledge of the disease. In the 600 non-small-pox cases the diagnosis proved right every time; of the 7400 cases pronounced to be small-pox, subsequent observation showed that two only were not small-pox—an error on the whole of one-fortieth of 1 per cent.

The Voluntary Service Fund.

It remained to make universally known such an invaluable method of recognising and defeating small-pox: and, accordingly, a campaign *with that object* has been steadily carried on during the past 28 years, with increasingly good effect. At first conducted by private individuals, this has latterly been shared by a group of voluntary workers, professional and lay, who form a nucleus known as "the Voluntary Service Fund," one of whose functions is to assist in freeing the country from small-pox. Among the main principles which actuate the Fund this comes first; that *by far the strongest defence against* small-pox is to attack it: *not to wait for small-pox to* attack us, and then to defend ourselves against it, but for ourselves to attack small-pox first, and to clear it out of the country. That is its first line of policy. Its second is educational—namely, to make the simple principles of small-pox diagnosis well known, not merely to every physician and medical officer *throughout the country*, but to every medical student, nurse, inspector, and intelligent layman as well. Those principles are as readily comprehended as the characters of chicken-pox. Dr. Ricketts, when called on to proceed to a case 14 miles away, used to say, "Of course, I am going up to see this case and to settle its diagnosis, but really it is not necessary. It is perfectly certain from Nurse ——'s *description* that the case is chicken-pox." Such a report has *often been made to myself. Modern methods* of small-pox diagnosis are now spreading steadily among all classes of the population: on one recent occasion the mistress of the house, in which a case of small-pox had occurred, who had gained her information from a well-known book on household medicine, was perfectly correct in her belief that she had *before her a case* of that disease.

The Fund (present address, 64, Great Portland-street, W. 1) has spared no efforts to continue the propagation of the ground-work *principles of modern methods* of small-pox diagnosis. It has met the increasing demand for handy and easily assimilated information on the subject by the publication of "The Accurate Diagnosis of Small-pox" *(third edition, 1927, 6d.), convenient for carrying in the* pocket. *Public authorities, such as counties, boroughs*, guardians, institutions, steamship companies and others, to the number of some hundreds, have distributed this post-graduate address to their respective medical officers.

Value of this Service.

Uniformly good reports have come in as to the value of this service, which has been found to meet the following indications:—

1. Medical practitioners have been forewarned and forearmed.

2. By these two simple measures 50 per cent. of the risk *of a* small-pox outbreak has been removed from a district, *and that at a cost which is negligible* in proportion to the risks involved. A warning is not enough. It is imperative also to forearm those who are warned. Experience shows that nearly every single small-pox outbreak in this country is due to one of the medical sentries, upon whom has been thrown the onerous duty of watching for small-pox, being outwitted *by this cunning invader.*

3. Medical practitioners are grateful for this counsel and help. It takes some of the weight off their shoulders; it enables *them to diagnose* with ease many of the simpler cases to which they may be called wherein small-pox is in question; it strengthens their position and that of the medical officer of health; it keeps the whole line of defence in touch and alert.

4. Local authorities are placed in a better position to meet public criticism as to the adequacy of their preparations beforehand against small-pox. When small-pox breaks out in a district it is noticed that public opinion asks more insistent questions than it used to ask, simply because it is better informed. To equip in this manner the whole line of medical sentries, and to keep them equipped, is the very first step in preventive preparation.

Our country stands in a very singular position in regard to small-pox. When it is realised that it is no uncommon event for one million cases to occur in any one year in the world at large (in 1918 there were 93,000 deaths from small-pox in *British India alone) that infection from* one or other of the innumerable foci is continually hammering at our doors: that on its arrival it finds 30 millions of people in England and Wales liable to take small-pox, the risks which we are daily running may be seen to be colossal. *There is nothing whatever standing between our people* and a small-pox catastrophe but the eternal vigilance of the medical profession.

About 12,000 of its members have been reached so far by the distribution of the pamphlets on diagnosis already mentioned. *So far* small-pox has not been noted to take hold in an area in which they have been widely issued. It is a fair inference that when all practitioners throughout the country have been so reached, one step at least will have been *taken on the way towards checkmating the entry* of small-pox and *raising our* security against its attack.

The Method in Brief.

There is here added, in brief, the method of diagnosis, commonly used by myself, stated imperatively for better *effect.*

Always carry the question in mind, "Can this be small-pox?", in any of its 50 or more *disguises*. Can it be *small-pox in its* pre-eruptive stage, simulating influenza, rheumatism, appendicitis? Can it be an initial rash? Can it be *hæmorrhagic small-pox?* Or small-pox in the stage of papule, of vesicle, of pustule, of crust, of recent *scarring?* Secure the very best light available. Examine the whole skin as comprehensively as possible. Postpone questions. Reply on personal first-hand observation. Set *little store by comparatively valueless evidence*, such as "shottiness," "umbilication," "cropping." Take a *rapid observation* of the whole case.

Then 1. Examine the relative distribution of the lesions. Go over *the whole surface methodically.* Assign a high value *to this head of evidence. Compare especially* the relative incidence as between face and front of trunk. Note the hands, *all the flexor surfaces, the axillæ, the feet.* Recall that a small-pox rash usually favours the relatively hyperæmic surfaces, and shuns the relatively protected surfaces, which *are not necessarily the same in a* footpad and a baby, in a *scrubber and a lady of affluence.* Before you give up, dot in the spots on a diagram of the figure, and count the spots of a discrete case. This heightens accuracy of observation, is an invaluable report and a convincing record. *Having done this, and* weighed up the value of the evidence, *dismiss it temporarily* from mind, and begin over again with

T[illegible]ty of the *lesions.* Avoid the face at [illegible] protected area, such as the arm or [illegible] likely to be more typical. Ex[illegible] the lesions on the chest and flanks. Also those on the specially irritated surfaces, as on the feet. Estimate the depth of the spots in the skin by rolling a fold of it between finger and thumb. Note the evenness and definition, or otherwise, of the outlines of the lesions; whether they are circular or not; whether they are tense or not; whether the covering envelope is substantial or not. Note this also in dealing with the milder form of small-pox. The individual lesions of small-pox may vary much in size, and be excessively minute. There occur cases in which the rash might be described as having been reduced to a miniature; but it is small-pox all the same. Presumed chicken-pox, or any rash of the first or second day should always be kept under further observation.

3. Try to estimate whether, and how rapidly, the rash has matured: that of small-pox undergoes regular development. Even at one observation it is usually possible to gain evidence of this. This evidence may be invaluable when it is otherwise difficult to reach a conclusion and no second opinion is at hand. Then place the case in observation and such isolation as is desirable; watch its development. Of itself, that may tell the whole tale.

4. Once more, start afresh. Examine the previous course of the case. Keenly sift the grain of the evidence from the chaff. Throw the latter to the wind. In estimating the value of this "history," the first in point of time, often the last in value, bear in mind the relative proportion between the stress of the onset and the quantity of the eruption.

These are the four cardinal heads under which to cross-examine a rash. Other points of varying value are the state of vaccination, and the degree of exposure to infection. This above all. Weigh the *whole* of the evidence taken together, and with the diagram. If necessary take time to consider it. Take a walk or a day to settle a decision sometimes as puzzling and as momentous as any in medicine. Keep your notes. Sign them. A useful practice is to write out a short memorandum, for personal reference, beginning, "My reasons for this decision are . . . ." Few cases of small-pox can elude scrutiny on these lines.

THE FUTURE OF MEDICAL PRACTICE.

To the Editor of THE LANCET.

SIR,—Your leading article of Jan. 5th and letters in your issues of Jan. 19th and Feb. 2nd assume only two possible organisations when looking to the future of medicine—a State service and private practice combined with the voluntary hospital system. I suggest that neither of these plans holds out much hope for the profession.

The Government (i.e., Civil Service) have tried to manage the mines and railways in the past, and have failed. Medical men who single-handed have had to deal on medical matters with the Ministry of Health or other Government departments are convinced that a State medical service is also doomed to failure.

The voluntary hospitals of the past have a wonderful record of service to the necessitous poor: they have long ceased to confine their attentions to this section of the community and to-day spend their time collecting money by wide advertisement, competitions, and other not too scrupulous methods, and at the same time compete more and more openly with the profession in taking money from those able to pay for sick attendance. The profession might be well advised gradually to withdraw their support from the voluntary hospitals. In passing it may be added that county and borough councils with their increasing number of clinics—widely advertised and supported by the rates—are competing very unfairly with private practice. It requires a united and strong profession to confine them to their proper sphere of preventive medicine.

In the scheme which follows the medical profession would control and manage their own industry. The general practitioner would be, as your leading article hopes, the backbone or keystone of the scheme. Let the country be divided into suitable areas—smaller in towns, larger in the country. The medical practitioners of each area would combine to elect a staff of consulting surgeons, physicians, oculist, aurist, and the rest. These consultants should live in their area and foster medical science there; the general practitioners would guarantee them the consulting work of the area, and in return control their public and charity appointments. A central group of consulting-rooms, operating-theatre, laboratories, X ray room, &c., with an attached nursing home would immediately be put up in each area, and later special clinics could be built for child welfare and the like, or a large hospital as the demand arose. In suitable cases the profession could take over voluntary or other hospitals already in use.

How should this be done? It is useless to expect busy practitioners to attend meetings, but in each area they could subscribe towards the part or whole time salary of a medical secretary, whose duty it would be to visit and get to know all the doctors, and in a year or so formulate a definite scheme for his area to adopt. The area secretaries should also be responsible to a controlling director chosen by the profession who would impart the necessary cohesion to the area schemes. A new branch of medical administrators would have to be trained at the various medical schools; by their sympathy and medical knowledge this group would help materially in the success of any hospitals or other undertakings started by the profession.

Finance.—A loan or debenture could be floated on the London market to finance all capital outlay required by the schemes of each area, the security being the buildings it is proposed to erect or take over and a first charge on the profits of the undertaking. Interest on the issue to be at a fixed rate. All doctors to hold a stated amount of stock, so that they may have a financial interest and stake in the success of their hospitals. The banks could be approached for loans in the early stages to secure running expenses.

Insurance.—A scheme of insurance for all salaried people and their families should be adopted, which those in a small way of business could contract into. Provided the insurance companies remembered that their first duty was to help and pay out, the scheme should prove adequate and reasonable for all sickness and accidents. Payment, whether to patients or direct to doctor, should be on a piece-work basis, and contract practice should be reduced to a minimum. All others could be treated on financial lines such as those in vogue at the Mayo Clinic.

On this plan I believe that a busy but not overworked life could be built up for all medical men and women, giving a fair return for labour done. Also we could control both the number and type of students entering the different medical schools, and gradually build up a profession of which medical men and the nation generally could be justly proud.

I am, Sir, yours faithfully,

FORWARD.

THE INCORPORATED CHIROPODIST.

MEMBERS of the Incorporated Society of Chiropodists and their friends sat down, to the number of about 180, to dinner at the Café Royal on the evening of Saturday, April 20th, the medical profession being represented not only by the Rev. A. W. Oxford, treasurer and one of the founders of the Society, but also by several well-known orthopædic surgeons and others interested in certain aspects of chiropody. The President of the Society, Mr. W. H. Taylor, in replying to a toast proposed by the Mayor of Croydon, spoke of the increasing prestige and position of the Society, which now had its own hospitals in London, Liverpool, Manchester, and Edinburgh, and was soon likely to have centres in other populous districts. The London Foot Hospital in Charlotte-street, W. 1 is already, it seems, outgrowing its premises and is likely to reopen with more endowed "chairs" elsewhere in a few months' time. In responding for this hospital, Sir Henry McMahon, its chairman, put in a claim for its benefaction by the bootmakers who were responsible for most of the ills which the chiropodist was called upon to alleviate. Dr. Oxford had genially described the bootmaker as an Attila leaving a trail of misery and pain behind him on his triumphant march. Sir Edward Penton, who accepted his description as the "big noise in the boot industry," took up the challenge and spoke with pride for the bootmakers who had been the creators of chiropody and hoped finally to be its death. Allusion was made in the course of the evening to the Registration Bill which has been read a first time in the House of Lords. It does not, as was at first intended, attempt to close the profession by penalising the unqualified person, nor does it claim for the registered chiropodist the right of diagnosing maladies of the foot. But it does prescribe a standard of training and equipment which has facilitated the convention reached with the consulting medical officers of foot hospitals. This rests on the limitation of the chiropodist's knife to the structures superficial to the true dermis and on his undertaking to practise his craft with antiseptic precautions.

SUCCESS OF CONTRIBUTORY SCHEMES.—Reports of the progress of hospital contributory schemes form a record of all-round success. The Torbay scheme was formed at the beginning of April, and in the first fortnight more than 3000 members joined. In five months the Southampton and District Hospitals Association numbers 10,000 members. The Radcliffe Infirmary (Oxford) scheme now has 70,000 members, and last year £31,000 was collected. Its federated hospitals and societies number 16 in towns, 346 in villages, 400 in firms and factories, 25 in colleges and halls, and 12 in Oxford city parishes. The Harwich Hospital scheme has added 653 to its membership during the past year; the basis is 3*d.* per week for families with incomes under £350.

An Address

ON THE

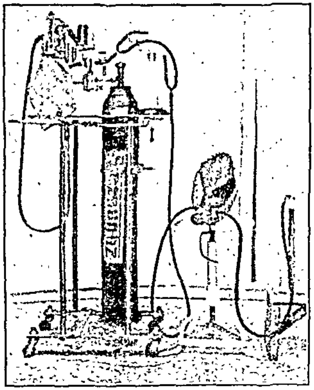
SURGERY OF THE ŒSOPHAGUS AND LUNGS.

Delivered before the Hunterian Society on Jan. 14th

BY DR. J. H. ZAAIJER,
PROFESSOR OF SURGERY IN THE UNIVERSITY OF LEYDEN.

THE subject I have chosen for this lecture is the experience we have had at the University of Leyden in the surgery of the œsophagus and lung, and the results we have obtained in this branch of work. When we began in 1909 we were strongly influenced by the work of Sauerbruch, and we were convinced that no real intrathoracic surgery could be performed without *differential* pressure apparatus. The feeling that positive or negative pressure *anæsthesia* apparatus was essential has more or less acted as a brake on the process of development of intrathoracic surgery, for those apparatus were expensive and difficult to handle. Its necessity led American workers to produce very costly but very magnificent positive and negative pressure chambers. In Leyden, however, we felt sure from the outset that such complicated apparatus was not necessary, and we therefore constructed a very simple positive pressure apparatus with which we were able to commence surgical procedures within the thorax. The engineer-constructor of one of the New York chambers once visited my clinic; when he saw our apparatus and heard our results he characterised the mechanism as "shamefully simple"!

FIG. 1.



Our outfit consists (Fig. 1) of the well-known Roth-Dræger apparatus for oxygen-ether and chloroform anæsthesia. On that is mounted a valve which directs the stream of oxygen through the pressure apparatus. A rubber tube divides into two channels, one passing through an ether bottle and the other going directly to the face-piece. The amount of oxygen passing through the ether is regulated by two simple pressure screws. The face mask is provided with a rubber edge and is held to the face by hand. We added a rubber balloon with a safety net round it in the belief that rather a high pressure would be necessary from time to time. From the mask the air passes through a rubber tube into a water ventilation chamber, wherein the pressure under which expiration takes place can be regulated. With this simple apparatus we have performed intrathoracic resection of the œsophagus with both pleural cavities open. So experience proved us right.

It is a curious thing that very different opinions are held about the value of differential pressure in thoracic surgery and the way to apply it. In France many surgeons think such an apparatus entirely superfluous. In America and in England surgeons and anæsthetists, such as F. P. de Caux, W. H. Romanis, P. H. Mitchiner, and Tudor Edwards think that the right way to apply the principle of differential pressure is by intratracheal insufflation, as introduced by Melzer and Auer in 1910. It is an extraordinary historical fact that what was believed in 1910 to be a new invention was described in the year 1513 by the famous anatomist Vesalius:—

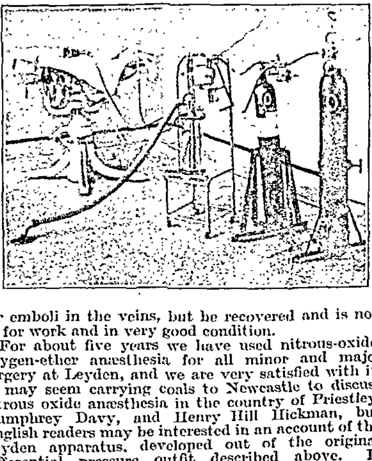
> Concerning the danger of suffocating the animal through the collapse of both lungs: to keep the animal alive one must try to open the windpipe and place therein a tube made from a quill pen or hollow reed. Therein must be blown, so that the lung swells and the animal gets sufficient air. With gentle blowing, the lungs swell so much as to fill the thoracic cavity. The heart regains its force and one can see very *splendidly the phases of the movement of the heart.*

Thus Vesalius in 1543!

In bilateral pneumothorax there can be no doubt that positive pressure apparatus is necessary for life, and I think Lilienthal is quite right when he says, in his well-known book on thoracic surgery, that it is unwise to neglect positive pressure even in unilateral pneumothorax. It is never possible to be certain that unilateral pneumothorax will not cause very grave symptoms, and the risk can be lessened by working under pressure. Our conclusion is, therefore, that positive pressure apparatus is essential for intrathoracic surgery, but it can be very simple, as at Leyden.

Another advantage of positive pressure anæsthesia is the prevention of air embolism in the veins, a point stressed by Sauerbruch in 1924 at the Surgical Congress at Berlin. One case in my clinic could hardly have been operated on with any hope of success without this form of anæsthesia. He was a young dentist with a large lymphogranuloma on the front of the neck and chest. The tumour had a very extensive venous anastomosis with the veins of the chest wall, and the risk of air embolism in cutting the vessels under the tumour would have been very great. He was operated on under an expiratory pressure of about 20 c.cm. of water, and even so there were small air emboli in the veins, but he recovered and is now fit for work and in very good condition.

FIG. 2.



For about five years we have used nitrous-oxide-oxygen-ether anæsthesia for all minor and major surgery at Leyden, and we are very satisfied with it. It may seem carrying coals to Newcastle to discuss nitrous oxide anæsthesia in the country of Priestley, Humphrey Davy, and Henry Hill Hickman, but English readers may be interested in an account of the Leyden apparatus, developed out of the original differential pressure outfit described above. It increasing difficulty in swallowing, so that at times food would not pass into her stomach at all. She had a high degree of pneumatosis of the stomach and colon with a curious position of the stomach, which was displaced to the right and had an hour-glass form. Thick rubber tubes passed easily into her stomach, and through them came an explosion of gas. Many observers regard this condition as cardiospasm, and the hour-glass form of the stomach as due to another spasm. When I operated on this patient I found her stomach rotated about its long axis. I tried to replace the pyloric part of the stomach, but it tended to relapse, and I therefore resected it after Reichel's method. This operation was unsuccessful. Not knowing what to do, I made a gastrostomy opening to let the air out, and that gave the patient distinct relief. If air came freely out of the tube the patient could swallow and her heart symptoms, such as extrasystoles, disappeared. When the stomach was blown up with air through the tube the bismuth meal did not pass through the œsophagus properly, but as soon as the air was allowed to escape, the meal passed into the small intestine (the stomach having been resected) with a run. The patient at times had many very disagreeable sensations, even when she was not taking food, when her air escape tube failed to work or was stopped by fluid. She was, therefore, provided with an apparatus to work under her clothing: the gastrostomy tube passes to a small flat bottle which catches and retains fluid, the air passing out by another tube which discharges at her shoulder. If the tube is stopped up, she presses a button, closing the outlet, and then blows the tube clear with a bellows. (Fig. 9.)

FIG. 7.

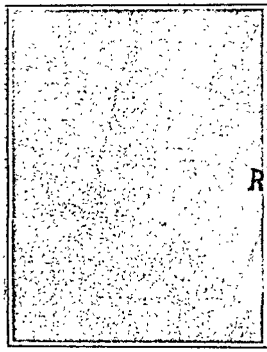


FIG. 8.

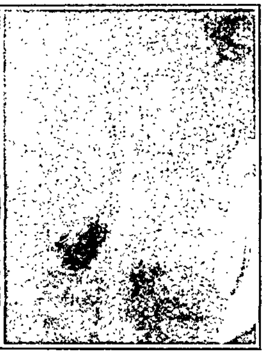

FIG. 9.

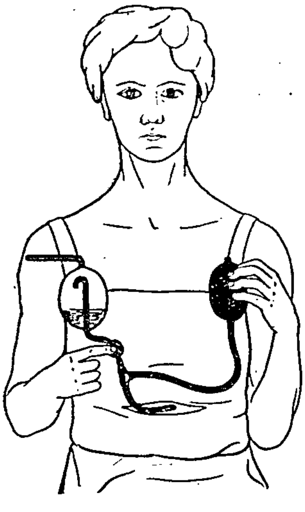


Imagine the position of a woman like this in the Middle Ages. She had many nervous symptoms which often made her disagreeable. She might well in those days have had a false friend who accused her of being bewitched. Very probably she would have been put to the floating test. She would have floated, proving that she was indeed a witch and ought to be burned because the devil in her made her float. But it would not have been the devil, but the bubble of air in her stomach—nowadays revealed by X rays.

ORGANIC STRICTURES OF THE ŒSOPHAGUS.

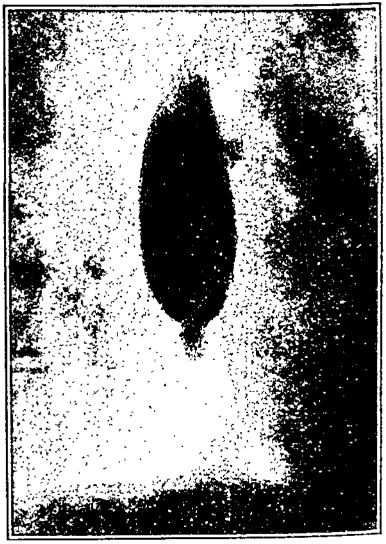
Organic strictures of the œsophagus as a rule can be dilated, and, in Anglo-Saxon countries, are dilated, by Plummer's method; the patient swallows a silk thread which passes well into the intestine and thus gives a purchase, so that the thread may be stretched and a perforated sound pushed over it through the stricture. I customarily treat these patients by von Hacker's method, picking the swallowed thread out through a gastrostomy and drawing soft rubber tubes through by its means. The thread must be left in for a month or more. Now a thread, whether it be of silk or of cotton, gives the patient a disagreeable sensation of cutting in his throat. A thin rubber tube will not cause this, but the patient will bite it through. If a thread is put inside the tube, it will not cut the throat, nor will the patient bite the tube through.

In several radiograms, I have seen the bismuth shadow end in a knob. I have no explanation for this phenomenon, but it seems to have some value in the differential diagnosis of benign strictures. (Fig. 10.)

A man of 49 who had had gastric trouble for 14 years had been treated for gastric ulcer by gastrostomy and jejunostomy. As he subsequently experienced difficulty in swallowing, his disease was taken for carcinoma of the œsophagus, a gastrostomy was made, and he was pensioned as an incurable case. In that condition he came to our clinic. The X ray examination revealed the condition shown in the illustration. (Fig. 10.) Œsophagoscopy showed a stricture only and no tumour. He swallowed a thread, which was fished up in the stomach by means of an operation cystoscope, and his stricture was then dilated in the usual way. He was cured and has remained in the best of health for five years. It is a curious sign of the times that he could not get back his position because he had been administratively declared incurably ill and pensioned. If the administration has declared you incurable it is very difficult to be administratively cured!

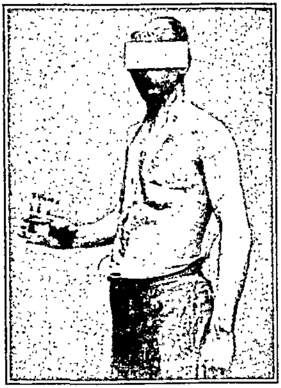
If a benign stricture cannot be dilated, the patient has to choose between going through life with a gastrostomy and undergoing a serious operation. For strictures situated higher up an antethoracic œsophagus may be made or a transthoracic operation may be performed. The latter is much the more dangerous and therefore is to be rejected. There is at Leyden a case of antethoracic œsophagus made after Lexer's method eleven years ago. The patient had swallowed hydrochloric acid and had a stricture some few centimetres above the diaphragm. It could not be dilated, so a short loop of small intestine was isolated, remaining connected to its mesenteric vessels and sutured to the stomach and to the skin, making a gastrostomy by Tavel's method. A skin tube was then constructed, and an opening for the œsophagus made in the neck. The two tubes were connected by little plastic procedures, which is perhaps the most difficult part of the whole treatment. The patient is now a man-servant in the hospital and eats normal food like a normal man with other servants, thus

FIG. 10.



proving the great and lasting value of this method. The picture (Fig. 11) shows him drinking a glass of water, which is still dilating his skin tube. Solid food enters the stomach in a few minutes.

FIG. 11.



For strictures situated low down, operations through the abdomen have been performed with good and lasting results. About thirty records have been published; we have so treated two men, both of whom were cured.

THE SURGICAL TREATMENT OF BRONCHIECTASIS.

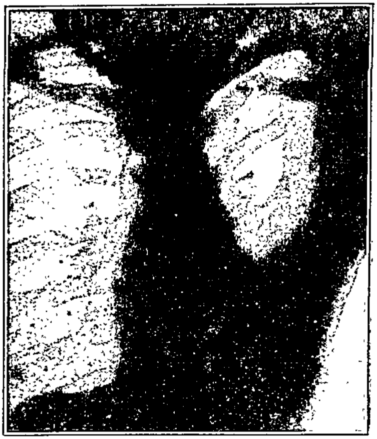
I have chosen the subject of bronchiectasis from the chapter of lung surgery because it is one that has developed along particular lines in our clinic, and we have now a very well-defined series of stages of treatment for these patients. The series is so designed that each stage comes to its climax in an operation, but the patient can be cured at every stage, and each operation lessens the danger of the succeeding stage if this is unavoidable. So that lobectomy, in addition to being an almost certain cure, is no longer a dangerous operation. I shall consider here only unilobar infections of the lower lobes, as these are, happily, the most frequent.

French authors are very satisfied with avulsion of the phrenic nerve and regard it as the "opération de choix." In England, as in Germany, the results do not seem very good, and we in Leyden have seldom seen much effect from this procedure. One patient only showed great improvement at first, but some months later she had a bad relapse. She had a fragment of bone in her right lower bronchus, and did not recover after removal of the fragment through the bronchoscope by my colleague Prof. Kan. She has not yet brought herself to accept further treatment. Another young girl with bronchiectases in the right lower lobe had a 50 per cent. improvement in the quantity of sputum, and the foul smell disappeared.

The second stage is a thoracoplasty. It must be a rule that a therapeutic procedure shall interfere as little as possible with the function of the healthy part of the organ. A thoracoplasty made over almost the whole half of the chest wall, as in the methods of Sauerbruch, Brauer, and Wilms, damages the upper lobes seriously; they are, therefore, not the methods of choice. My colleague Tendeloo has shown that a local thoracoplasty scarcely affects the whole lung, but brings about its effect chiefly on the parts underlying it. Therefore I think that an extensive resection of ribs over the affected lobe is a wise procedure, but it is essential also to remove the periosteum and the intercostal muscles. The conviction of this necessity was brought home to me by the case of a man of 20 whom I treated in 1914 by extensive subperiosteal resection of the seventh, eighth, ninth, and tenth ribs over the affected lobe. He was cured at the time, but had a serious relapse six months later. In the subsequent operation the newly formed plaque of bone and a large piece of the sixth rib were removed, and after that operation he recovered completely and has remained in excellent health for 13 years. At one time he had a large quantity of foul-smelling sputum and was socially quite inacceptable; he has now married a very nice woman. In another case I obtained complete cure by a local thoracoplasty over the affected right lower lobe, with removal of the periosteum and intercostal muscles. That girl has now been cured for seven years and is engaged to be married. Neither of these patients had any more sputum.

The removal of periosteum and intercostal muscles is not only useful in directly improving the therapeutic effect of thoracoplasty; it also lessens the shock of the operation. This is not to be wondered at, for we know that the absorption of bruised muscle tissue is a great factor in causing shock. It has, however, another advantage. If the thoracoplasty does not succeed or does not give enough relief, the next stage will be an intrathoracic operation on the same territory as the former operation. This will, therefore, become a soft tissue procedure, without requiring the removal of any more ribs. And there is yet another advantage. Perhaps the most important reason for thoracoplasty with removal of periosteum and muscle is that it causes adhesions of the underlying part of the lung at some distance from the site of operation. We know now that nearly all measures designed to lessen the danger of direct operations on the lungs are designed with the object of making adhesions, as, for instance, the subcutaneous gauze packings or paraffin deposits recently recommended so strongly by Sauerbruch. If the ribs are resected in the way I advise, the surgeon not only secures a greater and more precise therapeutic effect, but he also has a splendid preparation for the next stage if that becomes necessary.

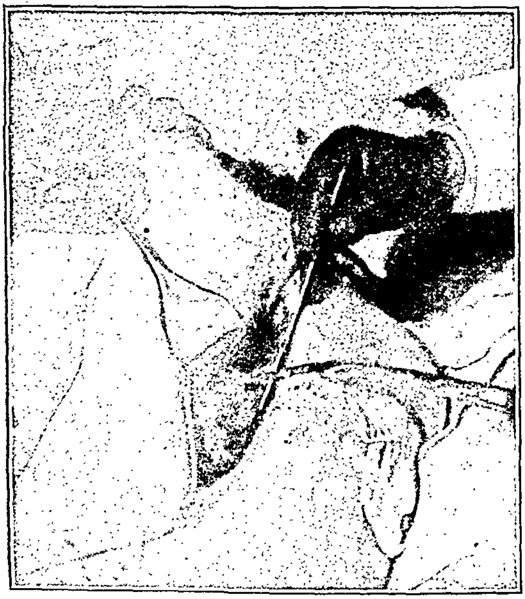
FIG. 12.



The next stage may take the form of either of two procedures: extirpation of the lobe or its slow destruction by burning. Sauerbruch has now abandoned his method of ligating the artery of the lobe in order to remove it. Graham's method of burning it out is associated with rather serious risk of air embolism and hæmorrhage. Resection of the lobe in the usual way carries with it great danger from shock and the chance of a permanent broncho-fistula. After losing a patient after lobectomy from shock and hæmorrhage I arrived at an intermediate stage between a thoracoplasty and a lobectomy—viz., the intrapleural plugging of the pleura after freeing the lobe as nearly as possible back to its root. This measure can give complete and lasting cure by causing compression of the diseased lobe, and in that case cure is attained with a minimum of danger and without the disagreeable complication of a broncho-fistula. X ray photographs show that the upper lobe is not collapsed after this procedure and it continues to function quite well. (Fig. 12.)

If this fails to cure the patient, because the lobe is too indurated to be compressed, then the last stage—so greatly feared until recently because it had a mortality of 50 per cent.—is really no longer very serious. If the plugs are well placed around the root of the lobe and it will not collapse, the surgeon will find on removing them that the lobe forms a more or less pedicled structure in the closed pleural cavity around it. It can be removed without shock by slow elastic stricture of the root. This can be done in the ward without pain when the doctor pays his visit. (Fig. 13.) The elastic tube is tightened every day and the lobe is choked, undergoes necrosis, and falls off—or can be removed by cutting some necrotic threads—in about a fortnight. Only very small broncho-fistulæ *appear, and the after-treatment is loose plugging of the* cavity with gauze. The cavity gradually becomes smaller and smaller, and at last the wound is closed, perhaps with, but possibly without, a small broncho-fistula. A German lady suffered from bronchiectases in her right lower and middle lobes. These lobes were removed and the wound healed. She has now been in good condition for about six months and has only a little sputum occasionally. Moreover, she has no broncho-fistula. The radiogram after operation shows that the right upper lobe contains air and the breath sounds are nearly normal.

FIG. 13.



METROPOLITAN HOSPITAL, HACKNEY.—An endeavour is to be made to raise £50,000, of which £20,000 will be required for building the new nurses' home and £10,000 for urgent schemes, such as the provision of new accident wards and improvements to the surgery.

A NEW DEVONSHIRE HOSPITAL.—Lord Mildmay, the Lord-Lieutenant of Devon, recently opened the new South Hams Hospital at Kingsbridge. The hospital includes a men's and a women's ward, each containing six beds, two private wards, and an operating theatre.

CHRONIC LYMPHOID LEUKÆMIA.

BY P. N. PANTON, M.B. CAMB.,
DIRECTOR OF THE HALE CLINICAL LABORATORIES, LONDON HOSPITAL;
AND
F. C. O. VALENTINE, M.R.C.P. LOND.,
ASSISTANT DIRECTOR.

Classification.

THE leukæmias are commonly divided into the myeloid and lymphoid types and each type is subdivided into an acute and chronic form. The subdivision is, in the myeloid form, both clinical and histological, since the acute and chronic forms are associated with different blood pictures. Acute myeloid leukæmia may arise de novo or less commonly as the terminal phase in chronic myeloid leukæmia, but in either event both the clinical state and the blood picture are entirely different in the two conditions. We are concerned in this communication with the state commonly described as chronic lymphoid leukæmia, and we understand by that a chronic process, of several months or years' duration, associated with enlargements of the lymph glands, or of the spleen or of both, accompanied by an anæmia, a considerable increase of the white cells, and a high relative increase of the lymphocytes. The lymphocytes are sufficiently like to the normal cells to be recognised as such and may be of the small or large varieties, or much less commonly the blood may show a more or less even admixture of the two types of cell. A pure type blood picture, that is, one in which the lymphocytes are nearly all small or nearly all large, remains constant during the whole course of the disease, apart from variations in the total number of cells induced by treatment.

The diagnosis of the leukæmias is necessarily concerned with the difficulty of distinguishing between primitive myeloblasts and primitive lymphocytes. For this differentiation we have employed at various times certain of the special granular stains, but have never been able to satisfy ourselves that any of these methods are capable of distinguishing between lymphoblasts and myeloblasts in their early stages of maturity. For diagnostic purposes we have relied upon Leishman's stain. When the small lymphocyte predominated, the typical cell as a rule showed a very small amount of clear blue cytoplasm, round a fairly typical lymphocyte nucleus. Double nuclei and other irregularities could sometimes be seen. Nearly always a small percentage of more primitive cells was present, which resemble in appearance the myeloblast as seen in chronic myeloid leukæmia. There does not seem to be any conclusive evidence to decide whether these cells are early lymphocytes or not, but in view of the activity of lymphoid tissue throughout the body in this condition, it seems probable that they are early lymphocytes or lymphoblasts.

When the large cells predominate many have a definitely abnormal appearance. Few cells show good azure granules, and many show a fairly deep blue cytoplasm. In these latter, which are probably young cells, there is a tendency for the nuclear meshwork to be coarser than in the adult lymphocyte where it is too fine to be clearly made out, while at the same time the deeply staining aggregations of chromatin, typical of the lymphocyte nucleus, are reduced. In a few cells the cytoplasm stains a greenish-blue and the nuclear network is even and undifferentiated throughout, an effect recalling the myeloblast. These may well be lymphoblasts.

The diagnosis from a Leishman-stained blood film between lymphoid and myeloblastic leukæmia may be on occasion difficult, and since it is dependent upon the opinion of experience may be fallacious. We claim, however, that such diagnosis, based upon the stained film alone, coincides with the clinical state of the patient. If the cells are adjudged to be myeloblasts the patient is in the acute state associated with the characteristic signs and symptoms typical of acute myeloid leukæmia. If the cells are lymphocytes a very different clinical condition is present. In the great majority of our cases the hæmatological diagnosis has been arrived at, in the first place, without reference to the clinical state. This appears to us evidence that we are able, in Leishman-stained preparations, to distinguish between atypical lymphocytes and the more primitive mother cells, lymphoblasts and myeloblasts. Since we have never seen the clinical state or blood picture in these chronic lymphatic leukæmia cases change to an acute lymphoblastic phase comparable to what may occur in myeloid leukæmia, and since the cells in all the acute leukæmias we have seen are either indistinguishable from the myeloblasts present in small numbers in the chronic cases, or evidently, as in the Rieder cell type, of marrow origin, we prefer to describe these acute cases as myeloid and not lymphoid leukæmia. The acute lymphoid condition is frequently described, and while we are not justified in suggesting that such a state does not exist we are acquainted with some published cases in which we should have unhesitatingly described the cells as myeloblasts.

Ætiology.

During a period of 16 years, from 1912 to 1927 inclusive, there have been 25 cases of chronic lymphoid leukæmia at the London Hospital. During the same period there occurred 89 examples of chronic myeloid and 58 of acute myeloid leukæmia.

The sex incidence of the leukæmias is of interest. In the chronic lymphoid state 20 were in men and only 5 in women, giving a ratio of 4 : 1. In the chronic myeloid cases 46 were men and 43 women, and in the acute myeloid 37 were males and 21 females. Chronic lymphoid is therefore the only form of leukæmia in which sex is an ætiological factor, and this finding appears to gain additional significance when one learns that the average age incidence of our cases is 55 years and that a recent history of impotence is not uncommon. Acting upon this somewhat slender evidence an extract of sheep testicle was prepared by the same process employed for liver extraction in the treatment of pernicious anæmia, and was administered by the mouth in one case of chronic lymphatic leukæmia in this series. No effect whatever was observed to follow the use of the extract.

The average age incidence in this series was, as has already been mentioned, 55 years. Only 2 cases were under 40, one being 20 and the other 35. The average age is therefore considerably higher than that of other forms of leukæmia.

Of the 25 cases, 9 were Hebrews, 13 were non-Hebrews, and the nationality of the remaining 2 cases was uncertain. This gives a ratio among the cases of known nationality of 1 : 1·4. The ratio of Hebrew to non-Hebrew patients in the London Hospital is not accurately known, but is more nearly in the neighbourhood of 1 : 10, indicating that the Hebrew race is particularly susceptible to this disorder.

Course and Symptoms.

The duration of the disease from the onset of clinical symptoms until death was only determined in 21 cases. In these the average duration was 2·17 years, but the series included a man and a woman who lived for 7 and 6 years respectively.

The lymph glands were palpably enlarged in all cases, with one exception, a woman who was only observed over a short period. The spleen was found enlarged on clinical examination in 20 patients, but in only 4 cases was the lower pole of the spleen found to descend below the level of the umbilicus. In 15 cases of the series the earliest symptoms were those of lymphatic enlargement, and the commonest site of this enlargement was in the cervical lymph glands. Four patients noticed abdominal swelling as an early symptom.

Analysis of the blood picture in this series shows that in 19 cases the predominant cell was a small lymphocyte and in 6 cases the large lymphocyte, and of these 6 cases all had glandular enlargement but only 3 splenomegaly, whereas 17 of the 19 small lymphocyte type cases had enlargement of the spleen. The average of the highest count was for the 6 patients with large cells 66,000 and for the 19 with small cells 208,000. The number of cases is small, but it would appear that in the large-celled lymphoid leukæmia there is a greater tendency to lower white cell counts and less splenic enlargement. The distinction between small and large lymphocytes is not absolute in the normal blood, and in these cases was not infrequently difficult. In most cases either the small or the large cell was overwhelmingly predominant, but in one patient—No. 18—the two types of cell were present on numerous examinations in about equal proportions.

Anæmia was present at some period in all cases, but in no less than 14 out of the 25 patients the red cells were in the neighbourhood of 5,000,000 per c.mm. or even above this figure in the earlier examinations. The colour-index was usually that of a secondary anæmia, but in some cases with a low red cell count the index rose to 1·0 or even higher.

Treatment.

The treatment of these cases did not differ greatly from that given in chronic myeloid leukæmia and consisted for the most part in arsenic given by the mouth and X rays administered over the splenic area. In the majority of cases X ray treatment consisted in massive doses given over the splenic area and resulted, as a rule, in a diminution of the white cell count. A comparison of myeloid leukæmia cases similarly treated showed that the subsequent leucopenia lasted longer in the lymphoid cases, and that the subsequent malaise was more severe and more prolonged. In our experience and in that of many others no example of cure of any leukæmic case has resulted from arsenic or X ray treatment, and we doubt if any prolongation of life is achieved. In chronic myeloid leukæmia, however, some diminution in size of the spleen, and occasionally a return almost to the normal size, results, and the patient is rendered correspondingly more comfortable. Also, accompanying the diminution of the white cells, patients do experience a certain feeling of well-being, and on psychological grounds alone the treatment is worth pursuing in the absence of any known remedy. In the chronic lymphoid cases, enlargement of the spleen is rarely sufficient to embarrass the patient seriously; the disturbances set up by the treatment may be considerable, and we feel strongly that this form of X ray treatment is, in the majority of cases, better avoided. On the other hand, X ray treatment of the lymphatic enlargements is often of great value and should always be employed when the glands are of sufficient size to inconvenience or by pressure to distress the patient. The lymphatic swellings nearly always subside rapidly under X rays. Case 5 of this series was first seen in January, 1921. He had marked enlargement of the spleen and of the lymph glands. The white cell count was 102,000 per c.mm., and after intensive X ray treatment his spleen became reduced in size and the white cells dropped to 3400. At this time (April, 1921) the patient was extremely ill and appeared to be almost moribund. Treatment was stopped, and as soon as the patient was fit to be moved he was taken to a convalescent home. He subsequently returned to his work as a carman, his white cell count rose to 50,000, and finally 343,000 per c.mm., and he continued at work with no treatment and in fair health until March, 1926, when he died of heart failure. Other cases in the series might be quoted as examples of the dangers of over-treatment and the possible advantages of no treatment at all.

Cause of Death.

The actual cause of death in the great majority of these patients is unknown, since death did not occur in hospital, and no post-mortem examination was obtained. Two patients who died in the London Hospital are of interest, because death in each case resulted from sepsis following upon a minor lesion. One of these patients was a man of 63 who appeared to be improving under rest in bed and X ray applications to the chest when he burnt his finger with a match while lighting a cigarette; the resulting blister became infected and he died of septicæmia in a few days. The other patient was a young Jew who died after four days' fever following the development of an alveolar abscess. We have known other examples of fatal sepsis occurring as the terminal event in lymphoid leukæmia, and the resistance of these patients to pyogenic infection appears to be extremely low.

We are indebted to the members of the staff of the London Hospital for permission to make use of the notes of their patients, and to Dr. Arnold Ash, formerly assistant director of the laboratories, for many of the blood examinations as well as for his help in collecting the records of the cases.

TREATMENT OF TABES DORSALIS AND ITS RESULTS.

BY W. J. S. REID, B.Sc., M.D. ABERD.,
M.R.C.P. LOND.,
HONORARY PHYSICIAN TO ANCOATS HOSPITAL, MANCHESTER.

THE treatment of tabes dorsalis advised in text-books is by no means uniform, and the prognosis from treatment is equally varied. The end-results are stated so indefinitely that it is hard to form any idea of what can be achieved. Leredde [1] certainly strikes an optimistic note, but his treatment of tabes is now really the routine treatment for an ordinary case of syphilis. Browning and Mackenzie [2] state that the "treatment of 62 cases of tabes leaves no room for doubt that it should be employed in every case. In some cases treatment will meet with complete failure, in others it will be accompanied by surprising benefit." The treatment spoken of is the ordinary routine treatment for syphilis by salvarsan remedies. Meirowsky and Pinkus [3] give even less encouragement, and advise that practically only one course of anti-syphilitic treatment be given, to be repeated possibly in six months, and that thereafter the treatment should be more or less symptomatic. Sachs [4] favours the energetic use of salvarsan combined with mercurials in the initial treatment of tabes dorsalis, but does not give a clear idea of the results, indicating rather what they may be in favourable cases.

To determine what could be achieved very careful observations were made of a considerable number of patients treated over a period of upwards of ten years. The patients were treated, except for some few short periods, as hospital out-patients or as private patients; confinement to bed or to an institution is not necessary or advisable and tends to depress the patient. A patient suffering from tabes should be encouraged to do his work as long as it is physically possible for him to do so. Tabes is still very common and is generally recognised to be a syphilitic lesion, the former designation of parasyphilis being both incorrect and unsatisfactory. With the great advance in anti-syphilitic treatment in the earlier stages by arsenical remedies it was hoped that the nerve affections would become much fewer. This hope has not been fulfilled, some even claim that tabes and other nerve conditions have shown an increase, for which the newer medication has been held responsible. It may well be that modern medication is in some degree responsible because of discontinuance short of complete cure. As Harrison [5] has suggested, the striking early effects of treatment may lull the patient into a false sense of security, so that he does not attend for treatment.

The aim of Ehrlich was to free the body from the disease by one large dose, the "dosis sterilisans magna." This was early found to be impossible in the majority of cases, and treatment was administered in series of courses of injections. The series have lengthened progressively with the passage of time, and even now very frequently fail to sterilise the body of its infection. If, however, complete sterilisation is not achieved the treatment has certainly deprived the body of much antigen, and the immunity level of a case incompletely treated is likely to be lower than that of an untreated case; this may well be a partial explanation of nerve complications arising later. The question of immunity in the late stages, and in fact in all stages of the infection, has been much neglected, though one might hesitate to subscribe to the views of Boeck [6] that practically no cases of neurosyphilis occurred in untreated cases. In this country cases are certainly seen where the onset of nervous symptoms is the first indication that an infection has occurred. The original infection must be long and carefully treated by the newer remedies if nerve lesions are to be avoided.

Treatment of Established Cases of Tabes.

Cases may, for purposes of treatment, be divided into two classes: (1) those not previously treated, or only insufficiently treated for syphilis; (2) those who have had long and apparently thorough treatment for syphilis by the newer remedies.

In Class 1 it has been my experience that the Wassermann reaction of the blood is positive, in some cases very strongly positive. In those cases which show any signs of tabo-paresis it has been always strongly positive with perhaps one exception; but such cases should be grouped rather under general paresis than under tabes, and their treatment by any method other than malarial therapy is hopeless. I have also usually found the W.R. of the cerebro-spinal fluid to be positive.

In Class 2, on the other hand, these reactions may be positive or negative, or may be now negative and after a little treatment may revert to positive, and vice versa. In other words, the reactions are not infallible tests of the condition, though they have much importance. A positive W.R. is always a very valuable sign. A negative W.R. after a series of positives may be of value as a guide in treatment, but an isolated negative reaction of blood serum or of cerebro-spinal fluid may have no value at all. The sign of greatest clinical value in my experience has been the cell count and to a lesser degree the globulin-content of the cerebro-spinal fluid. In tabetic cases before treatment counts have been obtained up to 90 cells per c.mm., and even higher in cases of tabes who had had no intensive treatment for syphilis.

In Class 1—that is, those who have had no treatment for syphilis at all, or only medicines by the mouth or inunctions, which latter, in this country at least, are hardly ever persevered with long enough to be effective—a system of treatment has been carried through in every case just as if the patient's condition was one of tertiary syphilis. This has always been persevered with until the blood Wassermann reaction has fallen considerably, sometimes to negative or in many cases to a weak positive. During this treatment the patients have been most carefully watched for signs of over-dosage or intolerance of the drug. The worst results of over-dosage are hepatitis and dermatitis, and at the first sign of either recourse has been had to thiosulphate of sodium, which is wonderfully effective in such cases. Special care in the treatment is required in all cases of tabes, and this care has much to do with the success. It is a disaster if hepatitis does develop, but this can be avoided by taking special care of the patient generally, and by not administering too large or too frequent doses of the drug. In my experience 0·6 g. of "914" is a large enough maximal single dose.

In the tabetic the vegetative nervous system is affected in every case. Very often intestinal action is sluggish, and while the whole action of the autonomic nervous system on the viscera is not yet understood its impairment must be assumed to reduce the efficiency of the viscera. This is of the utmost importance in a treatment which requires the administration over long periods of compounds which have a cumulative effect unless perfect action of the organs ensures their excretion from the body. Therefore tabetics must be frequently examined with the greatest care during treatment.

When three or more courses of injections have been given, each course amounting in all to about 5 g., with the same number of courses of bismuth or mercury given intramuscularly, and when blood Wassermann reactions have yielded lower results, this class of case can be grouped with the second class as having undergone sufficient general antisyphilitic treatment for some treatment to be undertaken, directed specially to the nerve condition. A patient treated as above has generally improved very considerably, but his nerve symptoms may or may not have been subdued. In 1916 I tried intraspinal therapy after the method of Swift and Ellis[7] on ten patients, but discarded it because it was not without pain and the amount of drug or its derivatives that could be introduced into the theca seemed to be too small to be of value. The method did not yield the results claimed for it.

Reinforcement by Drainage.

A method of "reinforcement by drainage," if the terminology be permissible, was therefore tried and has yielded much better results; it is the method now used in all my cases. The procedure is as *follows :—*

An intravenous injection of 0·25 to 3 g. of Silber-salvarsan is given. This drug is sold by Meister, Lucius, and Bruning, and is, in my opinion, the finest preparation for the treatment of nerve lesions. Within ten minutes a lumbar puncture is done with the patient in the sitting position, and as much cerebro-spinal fluid as possible is drawn off until discomfort is caused. If the fluid is withdrawn slowly through a small-bored *flexible needle of White's Jeanselme pattern 50 c.cm.* or more can be withdrawn slowly before any occipital headache is complained of. The patient is left lying down for six hours, and then goes home and remains in bed for 24 hours. Lumbar puncture done with novocaine is not painful, and with a fine needle the discomfort is minimal. This operation was performed five times at fortnightly intervals. In the intermediate weeks the patient had an intravenous injection of Silber-salvarsan without the lumbar puncture. At the end of a course the cerebro-spinal fluid was found to have reverted nearly to normal in a large proportion of cases, and in all of them was much improved. This course has been repeated twice or three times with intervening periods during which the patient was on bismuth or mercurial treatment, or being treated with iodide of potassium or with tonics.

*This method was found much superior to intra*spinous therapy and has caused no ill-effects in any case. The idea originally underlying the treatment in my mind was that by reducing the pressure on the fluid side of the choroid plexus and increasing the concentration of arsenical bodies on the somatic side of the plexus, the fluid, which has to be regenerated quickly, might be expected to contain a higher amount of the arsenical body or its derivatives than otherwise, especially as there is much evidence that the formation of the fluid is by osmosis and not secretion (Fremont-Smith).[8] It must be borne in mind, however, that drainage of the cerebro-spinal fluid is per se of the greatest value in cases where there is inflammation of the meninges, and may be relied on to be beneficial in tabes, so long as an increased cell count is present as evidence of inflammation. There is therefore double benefit in drainage. Probably the best time to perform drainage is just after intravenous injection. Although the fluid drawn off has been examined on each occasion, a sample has always been drawn off one month after the last drainage of the treatment course *and examined as to cell-content, globulin-content,* and Wassermann reaction. A sample of blood was submitted to the Wassermann reaction at the same time. If the cell-content was down to normal level and the Wassermann reaction of the fluid was negative, the patient was continued under the ordinary treatment for syphilis, on a less intensive scale, for a year at least, the periods of rest between courses being progressively increased. A year later the fluid was examined again, and only in those cases where the cell-count was beyond the normal *limits of seven cells* per c.mm., or the W.R. of the fluid was definitely positive, was another intensive course of therapy directed toward the nerve lesion. The W.R. of the blood serum may have yielded a positive or negative reaction, but in either case a course of ordinary antisyphilitic injections was carried out every six months.

Results.

In the period 1916 to 1927 104 cases of tabes dorsalis have been treated in this way, and, while periods of remission are often so long that it is difficult to assess the value of treatment, sufficient time has perhaps elapsed for a claim to be made. The result of treatment in these cases has been to reduce the cell-content of the cerebro-spinal fluid to the normal limits in every case and to maintain it there. The W.R. of the fluid has been reduced considerably in all cases, and in most of them is now negative, while the W.R. of the blood serum has been in many cases reduced to negative, or sways between negative and weakly positive when tested over a period of years at three-monthly intervals. In a disease like tabes cure, in the strictest sense of the term, cannot be spoken of or seriously considered. Nerve-fibres inside the dura mater, once destroyed, can never be regenerated, and therefore all patients when examined clinically still reveal the picture of tabes. The knee-jerks are absent and the light reflex is gone, but the disease has been arrested in its progress and, in some exceptional cases, is believed to have been eradicated.

The general condition of all the patients improved very considerably. Many of them when first seen were very asthenic and almost emaciated; in fact, in my experience the disease is usually accompanied by wasting, accentuated by the diminished muscular tonus. In some cases the increase of weight was very striking, and an increase of up to 2 st. was common. The improvement in the lightning pains has been very marked in every case. Here the effect of drainage of the cerebro-spinal fluid is especially helpful; at the *end of a series of five punctures the pains were in* every case much reduced in frequency and intensity, and ceased to be "lightning" in nature. In some cases, especially those which were advanced, the pains altered in character and the patients complained of a dull persistent pain. This may be due to the fibrotic process round the nerve roots, and if so it is hard to see how these pains can be removed, except by section of the nerve roots. They are akin to girdle pain, which is not influenced by treatment. The visceral crises responded equally well to treatment. In the acute gastric crises atropine sulphate injected subcutaneously with or without morphine has been found most effective; a single hypodermic injection could be depended on to give rest and relief for four hours, and after one or two repetitions the crisis had passed off. The anæsthesia which is universal in the disease was, of course, unaffected by treatment. The bladder symptoms were benefited and in many cases were so much subdued as to be almost gone. They were ameliorated in all the advanced cases. The arthropathies of the disease, the Charcot's joints, appeared *in one or two cases during treatment, and even after* treatment was finished, but as this is a trophic lesion its onset is not proof of progression, but of a lesion which has already progressed sufficiently to cut the nerve-supply to the part, and there is no reason to hope that any treatment will be able to restore this innervation. The same is true of the mal perforans, though no case of this appeared during or after the treatment. Those which were already present healed up with care and rest, and treatments were not suspended on their account. It was hoped that drainage of the cerebro-spinal fluid, by reducing pressure, might help optic atrophy, but that hope was not fulfilled in any case, and there is no reason to anticipate any improvement with present remedies.

In some patients the optic atrophy seemed to be arrested, and this is the most that can be hoped for; in some others it progressed very rapidly to complete blindness, but not more rapidly than in untreated cases. There is no reason to believe that treatment by arsenical remedies accelerated the atrophy, and therefore nothing to indicate withholding the drug. In one or two cases tryparsamide was used, but the danger of optic atrophy so strongly insisted upon in the literature made a sufficient trial of that drug undesirable. On the other hand, the pareses of the orbital muscles completely disappeared under treatment. The ataxia did not improve directly as a result of treatment, but the improvement in their general well-being enabled the patients to take more exercise, so that the process of re-education progressed very rapidly, and as they regained confidence they complained less of their ataxia.

Conclusions.

Tabes dorsalis should be treated very thoroughly, and the method of lumbar puncture in conjunction with intravenous medication can be relied upon to restore the cerebro-spinal fluid to something approaching normality.

In most cases the progress of the disease can be arrested if treatment is persevered with.

In spite of treatment optic atrophy may progress and become complete.

The improvement in the general condition is very considerable and the increased efficiency of the patient very striking.

Naturally the results achieved vary with the stage of the disease at which treatment is undertaken. The earlier the stage of the disease and the less nerve destruction that has occurred the better the results of treatment will be, but in practically no case should treatment be refused.

CALCULOUS ANURIA.

BY H. P. WINSBURY WHITE, F.R.C.S. ENG.,

ASSISTANT UROLOGICAL SURGEON, ST. PAUL'S HOSPITAL FOR GENITO-URINARY AND SKIN DISEASES; ASSISTANT SURGEON, EAST LONDON HOSPITAL FOR CHILDREN; UROLOGIST, ST. JOHN'S HOSPITAL, LEWISHAM.

THE suppression of urine due to calculus may be complete or partial. Although it occurs at all ages in both sexes it is most common after 40 and more frequent in men than in women. The cessation of the renal function may be caused in one of the following ways: (1) obstruction to the escape of urine from both kidneys; (2) obstruction to the escape of urine from the only kidney; (3) occlusion of one kidney and inhibition of the other, which is partly damaged; (4) as the climax of a gradual but progressive renal failure resulting from long-standing and extensive bilateral calculous disease, occurring quite independently of renal occlusion; severe exertion is often the means of precipitating an attack by causing the misplacement of a stone into a position where it can obstruct.

The calculus may be in the ureter or the kidney. In the ureter it is most commonly found in the upper third, next most commonly in the lower third. In the kidney it is sometimes quite a small stone situated in the pelvis, of which it blocks the outlet. Anuria in a kidney containing widely distributed stones generally means considerable permanent impairment of renal function and is not likely to be remedied by surgical measures. There is experimental evidence to support the belief that reflex anuria may result from unilateral disease, the kidney on one side being perfectly healthy. The influence of the diseased kidney on its supposedly healthy fellow is spoken of as the reno-renal reflex. Goetzl, experimenting on three dogs, produced complete anuria in one for 65 minutes by raising the pressure in the renal pelvis. In the other two, although he did not succeed in producing complete anuria, he obtained marked diminution in the amount of urine secreted. Rovsing has reported three experiments in which he produced complete anuria for periods of two or three days by clamping the pedicle of one kidney. The anuria persisted while the clamps were in position and ceased when they were removed. Israel has reported two cases illustrating the same process clinically. In each of these, after removing an obstructing stone, cystoscopy showed a return of the urinary flow from the opposite side. Although these observations all establish conclusively the influence of a diseased kidney over the function of the other, most authorities hold that the condition of complete anuria depends upon disease of both kidneys and that the microscope will always reveal some pathological change in the supposedly healthy kidney. Kelly and Burnam state the position by saying that there is no case in the literature where the patient has had complete anuria and died of uræmia, and at autopsy a stone has been found blocking one ureter while the kidney on the other side was healthy.

A kidney whose secreting function is suppressed is swollen, engorged, has small hæmorrhages under its capsule, and contains blood-stained fluid under tension in its pelvis when the outlet is blocked.

Clinical Features.

The *absence of urine from the bladder* on catheterisation when this organ has not recently been emptied establishes the diagnosis of anuria in the initial stage. The period of anuria has two principal phases: in the first the general health of the patient does not give any indication of the gravity of the prognosis, and the diminished urinary excretion may be the only warning of the impending disaster. The patient may be able to carry on in this way for several days without much inconvenience, or the more serious symptoms may supervene much more suddenly, and headache, irritability, nausea, constipation, and flatulence rapidly leads into the period of intoxication. This is indicated by drowsiness, slow pulse, subnormal temperature, and slow and irregular respirations. These give place to the terminal stage of dyspnœa and coma.

Pain is a variable symptom. Sometimes it is difficult to elicit any history of suffering; other patients readily complain of aching in the loin or of attacks of colic. It is of great importance to establish clearly in which kidney the pain is more recent, for this is probably the least damaged and therefore the one which the surgeon should attack first. A long-standing history of pain in one kidney region, and a recent account of the same symptom in the opposite organ, is a strong indication that the latter is the one which demands the surgeon's urgent attention.

Tenderness may be expected over one or both kidneys and ureters, but when the patient has been living entirely on one kidney tenderness will usually be found only over the recently functioning organ.

Cystoscopy may show the offending stone protruding from the ureteric orifice or bulging the bladder wall just above it.

A *radiogram* of the whole urinary tract is essential.

I recently saw a woman of 31 years of age in a state of uræmic coma. There was a history of pain in the left side and anuria for several days, and a previous history of the passage of small stones at odd intervals. No other helpful facts about the case could be obtained. In the right lumbar region posteriorly there was a small sinus leading towards the right kidney region. There was no urine to be seen coming from the sinus, which was obviously of many years' standing. No radiogram was available. The conclusion was that the right kidney had long ago been destroyed by calculous disease, with perinephric suppuration and sinus-formation, and that the left kidney had now become occluded by a stone. Operation was hurriedly carried out and a small calculus was removed from the pelvis of a somewhat engorged left kidney. The patient died on the same day. The post-mortem examination revealed that the right kidney was represented only by a mass of fibro-fatty tissue surrounding a number of calculi.

Differential Diagnosis.

The identification of the cause of renal failure involves a consideration of a fairly wide range of diseases, of which the following are the commonest. They are not difficult to detect on carefully considering the history and clinical features: bladder growths, prostatic enlargement, urethral stricture, pelvic tumours causing back pressure on the ureters. Kidney damage from drugs such as lead, mercury, and arsenic has to be excluded, while anuria may also arise as a crisis in the course of an acute or chronic nephritis. Post-operative renal failure following operation on the urinary tract or elsewhere offers no difficulty in diagnosis.

Treatment.

Non-operative Procedures.—In early cases, when the ureter is blocked near its lower end by a stone that is not too large to pass into the bladder, ureteral contractions may sometimes be initiated and the stone passed by distending the bladder with fluid. Heitz-Boyer and Elliot reported a case successfully treated in this way. The patient had suffered from anuria for 48 hours. A ureteric stone the size of a haricot bean was passed within an hour of distending the bladder with fluid and urinary secretion was at once re-established. Other similar cases have been reported.

When this method fails after a short trial ureteric catheterisation should be tried, for the passage of the catheter beyond the stone may relieve the crisis by re-establishing the secretion of urine. Two catheters can sometimes be passed in this way, giving still more efficient drainage. These should be left in position for two or three days if the symptoms of anuria continue to subside. At the end of this time the patient is in a much more satisfactory state to undergo an operation. If no result should follow the successful passage of the catheter up one side the opposite ureter should be catheterised also. A little sterile water injected into the renal pelvis will sometimes induce peristaltic contractions and initiate renal activity. In some cases the kidney substance is so badly diseased and has such poor capacity for recovery that there is no response to any of the above measures. Operation in such circumstances will only hasten the patient's end. It must always be kept in mind that the process of kidney destruction from calculous disease is an insidious one and that the onset of total cessation of urinary secretion may be but a small step from the diseased condition which has preceded it. In other words, the final failure is not due to a mechanical blocking by stone, but is simply the terminal stage of chronic renal disease. The failure of any surgical measures is assured in such a case. All the means of relieving and inducing the urinary flow by dietetic and medicinal means must be undertaken energetically. Milk diet should be given to relieve the kidneys of additional work. Hot packs or hot air baths will promote the excretory activity of the skin, and diuretics such as caffeine, digitalis, and Contrexèville water will stimulate the renal function. Saline purgatives should be administered to increase the escape of fluid by the bowel.

Operative Procedures.—The purpose of an operation in a case of calculous anuria should be to provide for the unobstructed flow of urine with the minimum of operative shock. Prolonging the operation by searching for a stone is very likely to be the means of turning the tide against the patient. Therefore, when the surgeon has no idea where the stone lies and the general condition of the patient is not good, the rapid restoration of the urinary flow should be accomplished in the simplest possible way. If ureteric catheterisation and other non-operative measures do not establish this, immediate exposure and drainage of the kidney should follow. When the stone lies in an easily accessible part of the ureter, such as the upper or middle third, or in the vaginal fornix, it may be removed at once. In rare instances the calculus has been dislodged from the ureteric orifice by bimanual manipulation. Pyelotomy should be carried out only when the stone is known to be located in the pelvis, and when it is found on cutting down that this part of the kidney can be promptly reached. Nephrotomy is indicated when the stone is in the pelvic portion of the ureter, when the calculus is in the renal pelvis and found to be difficult of access, or when its exact location is not known.

In all cases in which there is doubt whether the symptoms are due to stone, a radiogram of the whole urinary tract must be obtained before operation. If this is not forthcoming without a dangerous delay the surgeon will have to decide whether the clinical features of the case justify him in proceeding with his search without this information. If it is not definitely known that a calculus is present, he must bear in mind that on exposing the kidney a prolonged search for the stone will considerably diminish the patient's chances of recovery. He should be content, therefore, with establishing the fact that the renal pelvis and the ureter are not obstructed, or, if either is, with relieving the obstruction by the quickest possible means.

Prognosis.

The success of surgical interference in cases of calculous anuria depends chiefly upon the fact that the suppression is due to obstruction by a stone, the length of time the condition has remained unrelieved, and independently of the foregoing, the pre-existing amount of renal damage. In considering a large series of cases it is found that if no means are taken to relieve the obstruction less than 30 per cent. recover spontaneously. The onset of uræmia makes the outlook extremely grave, whether surgical interference follows or not, but successful operations have been reported. Uræmic symptoms do not usually supervene until five or six days after the onset, and the mortality rises steadily with each day's delay in operating. Figures published by Huck show that with operation before the fourth day there is a mortality of 25 per cent., and before the sixth day of 42 per cent. The best operative results are obtained in cases in which the signs of renal failure from calculous occlusion of an otherwise healthy kidney have not come on gradually but suddenly.

AMBULANCE CASES AT BALHAM.—Dr. W. L. Maccormac, the medical superintendent, in his annual report upon the work of St. James's Hospital, Balham, states that during 1928 9105 ambulance cases were dealt with. In the winter months "many of the wards are seriously overcrowded," and it is proposed to provide a new administrative block and a small isolation block.

OPPORTUNITY FOR TRAINING IN DIETETICS.—A Department of Dietetics was established at University College Hospital last November to deal with the special diets, particularly in diabetes, nephritis, and gastro-intestinal disorders. This department is under the control of a member of the honorary medical staff and in charge of Miss E. M. Marshall, B.Sc., who is a fully qualified dietitian. It is hoped later to inaugurate a school for the training of dietitians, with adequate courses of lectures combined with the practical work, for which fees will be charged. At present, while such lectures are not available, there is an opportunity for training one or two pupils in practical dietetic work; the course would last six months, and the instruction would be given free. Candidates should preferably possess a degree in domestic science. Further information can be obtained from the matron of the hospital.

Clinical and Laboratory Notes.

THE VALUE OF JOINT AUSCULTATION.

BY C. F. WALTERS, F.R.C.S. ENG.,
SENIOR SURGEON, ROYAL INFIRMARY, BRISTOL.

THE out-patient surgeon is often confronted with a painful joint, generally a knee, in which initial trauma may have been slight or absent, in which nothing abnormal is visible to the eye or in skiagram, and nothing unusual can be felt. Fifteen years ago these joints, not apparently due to tubercle or syphilis, were treated by massage and other methods in vogue. Some appeared to recover, but in others the pain persisted and the patient not infrequently drifted elsewhere. In other joints with a similar history, fine grating could be felt on movement, although skiagrams usually showed nothing abnormal. Yet, again, other joints would have a still coarser grating, palpable and audible with the unaided ear, and in these well-marked osteo-arthritic changes were seen with X rays. When the first type of joint—in which nothing abnormal could be found—is auscultated, a very fine grating, almost like the hair crepitations in the lung, is heard, especially at the end of complete flexion and extension. The crepitations are of the same timbre as those heard in the coarser types, and when I first detected them I realised that one was probably hearing the earliest changes produced in the joint by the same factor that produced the coarser grating.

When one listened to other joints, as well as the joint complained of, one found that a similar condition often existed in wrist, elbow, shoulder, jaw, and knee-joints, of which no complaint had been made. Only that joint which had suffered trauma became manifest by the appearance of pain or discomfort; the other joints, though affected by a common cause, remained "latent," sometimes to become manifest later on through trauma or advancing age.

A General Auscultation of Joints.

In order to determine whether the auscultation of joints is of any value in distinguishing different forms of joint affections, it was thought advisable first to auscultate a large number of joints in hospital patients admitted for other than joint affections. For this reason wrists, radio-ulnar, shoulders, temporo-maxillary, and knee-joints were auscultated, in ten patients in each half decade, five male and five female (except those below the age of 10, when the sexes were not separated), from 1 to 80 years of age; the cases were unselected, save for sex and age. Some 1600 joints in all were examined under passive movement. As a result of past experience the joints were grouped into smooth (S), rough (R), grating †, grating ††, and grating †††. Joints which crackled, as distinct from grating, were also noted, but not regarded as pathological; for the number of crackling joints lessened rather than increased as age advanced.

The terms I use are as follows:—

The *smooth* joint was one that was quite inaudible to the stethoscope throughout its whole range of movement.

The *rough* joint was audible as the faintest roughness through any range of movement, to a very coarse roughness, as distinct from grating, heard throughout the whole range of movement of the joint.

The grating † joints, or those of the first degree of grating, were those in which a fine hair-like crepitation could be heard by stethoscope at the end of full flexion and extension only, or sometimes over larger ranges of movement, but was quite impalpable.

The *grating* †† joints, the second degree of grating, were those in which the grating was louder and more coarse, heard through part or whole of the joint movement, and often palpable.

Grating †††, a louder and still coarser type, was heard through the whole range of movement, and could not only be readily felt but was often audible to the unassisted ear. This should not be confused with the crackling joint (C), the noise of which is probably often extra-articular as well as due to cartilage movement, as in the temporo-maxillary articulation.

Sites of auscultation were chosen as free as possible from hair, and on the flexor surface of the wrist, over the radio-ulnar joint to the outer side, in front of the shoulder, over the temporo-maxillary joint in women, but a little anterior to it in men, to avoid hair, and on the inner side of the knee over the most prominent part of the internal condyle of the femur.

Previous or existing foci were inquired for in ear, nose, throat, teeth, vagina, and rectum in most cases; bowel habit during life, constipation or otherwise, was ascertained, and rheumatism and other illnesses noted. Past or present possible foci existed in 80 per cent. of the cases examined.

It will be seen in Table I. that, roughly speaking, there is a steady increase through each decade except the sixth in the audible as opposed to the smooth joint. Whereas in the first ten years of life 98·5 per cent. of joints were smooth, and only 1·5 per cent., or three joints in 200, were audible, in the last ten years (70–80) only 18·5 per cent. were smooth, and 81·5 per cent. were audible. Moreover, in the last decade the most severe type was present in 16·5 per cent. of cases; this did not appear at all until the fifth decade. The percentage of rough joints (R) after the first decade does not vary more than 5 per cent. until the last two decades, when it falls by half, to be replaced by the more marked forms of audibility, the †† grating and the ††† type increasing in a marked degree. There is a steadily ascending ratio of all forms of audibility from 1·5 per cent. to 81·5 per cent. with the exception of the sixth decade, but even here the more severe forms of joint grating exceed the earlier figures.

TABLE I.—*Summary of Joints Auscultated in Each Decade, with Classification.*

TABLE II.—*Sex Distribution.*

Type of joint.	Male.	Female.
Total	398	427
Rough	184	121
Grating †	172	207
,, ††	75	61
,, †††	8	35

Grating of the second degree is often found in painless joints, but is more likely to be associated with pain or discomfort than is the lesser marked grating or roughness. Grating of the third degree is much more often found with complaint of pain or rheumatism. Of 47 cases with grating †† joints, 25 complained of rheumatism, and 22 had no rheumatism. Of 16 cases in which grating ††† was found, 14 complained of rheumatism and two only did not complain. The most severe grating preponderated in females as 4·37 to 1 male. These figures suggest that whatever may be the cause of the grating, the more arduous work of males is not a factor in its production.

Crackling Joints.

As Table III. shows, "crackling" appears to be least marked in the last decade and most frequent between the ages of 30 and 40. It was heard most frequently in the shoulder-joints, two-thirds as often in the jaw, and one-third as often in wrist, radio-ulnar, and knee-joints. It was not regarded as pathological.

Totals ..	17	21	57	43	17	

Conclusions.

(1) Auscultation of joints may reveal a very early stage of roughness or grating, which is not recognisable by other means.

(2) As age advances the grating appears to increase steadily until it is manifest to touch and the unaided ear; in the most advanced stages its cause is visible in skiagram as the joint changes of osteo-arthritis.

(3) These joint sounds are to be heard, by stethoscope, in a large number of hospital cases, unselected save for sex and age, and admitted for other than joint affections.

(4) The number of affected joints, as a whole, preponderate in the female as 55·7 per cent. to 44·3 per cent., the most markedly affected joints, however, existing in the female as 4·3 to 1 male.

(5) These figures suggest that the more arduous work of the male is not a factor in producing these sounds.

(6) A possible past or present focus existed in 80 per cent. of the cases examined.

(7) The number of joints with auscultatory changes becomes more numerous as age advances—from 1·5 per cent. to 81·5 per cent.

(8) The sounds heard, judging from their wide distribution through many joints, are probably the result of changes produced by a blood-borne infection or intoxication. This is confirmed by the fact that the stethoscope will also often reveal, in the same subject, many other joints in which disease is latent and as yet unheralded by discomfort or pain.

(9) The removal of a focus may render a manifest joint again latent, but it will still be audible to the stethoscope and sometimes to touch.

(10) In patients with osteo-arthritis in one joint, many other joints will, by stethoscope, almost invariably be found to be involved in a lesser or greater degree, of which the patient is often quite unconscious.

I should like to thank my late dresser, Mr. K. H. Pridie, for investigating some of the cases in the last decade.

A CASE OF
GOUTY CHEMOSIS TREATED WITH ATOPHAN

BY V. ST. L. PINNOCK, M.B. BRIST.

THE following case seems worthy of record:—

A woman, aged 60, on June 4th, 1928, complained that her right eye was protruding from its socket. Five years previously she had had an apoplectic attack affecting the right arm and right leg with loss of speech. The use of the right arm and leg had later returned w [illegible] the latter.

On examination I noticed that she still had some difficulty of speech and also very slight dribbling of saliva at the right angle of the mouth.

There was considerable œdema of the bulbar conjunctiva of the right eye, which projected well beyond the margin of the lids, but there was no exudation of pus. The cornea was unaffected and appeared to be surrounded by a wall of gelatinous-looking material tinged slightly red. The iris was regular in outline and of good colour; the response to light was immediate. The anterior chamber was shallow and there was a senile cataract of the lens which deterred perception of hand movements but allowed perception of light. She said she had been treated for a "detached retina in this eye" in 1919. She had not been taking potassium iodide for months before the chemosis. The eye was not painful.

The left eye was corrected by a heavy minus lens, thereby maintaining some acuteness of vision. The tension was normal, the cornea clear, and the iris regular in outline and of good colour, reacting to both light and accommodation. The systolic blood pressure was 170 mm. Hg and the radial artery at the wrist was thickened.

Atophan, grs. 7½ three times daily, was prescribed, sodium bicarbonate, grs. 10, being taken five minutes previously so as to neutralise any free acid in the stomach. She was also recommended to use zinc sulphate eye-washes poured on the eye from an undine. Four days later (on June 8th) the chemosis had almost disappeared. She was next seen on Oct. 3rd and informed me that the eye affection cleared up completely following the atophan treatment in about seven days altogether. There has so far been no recurrence of the trouble.

CONFERENCE ON MENTAL WELFARE,
WESTMINSTER.

THE Central Association for Mental Welfare held a conference at the Central Hall, Westminster, on April 25th and 26th. At the first session the subject was the Effect of the Local Government Act, 1929, on the Work of Local Authorities under the Mental Deficiency Acts.

The chair was taken by Sir LESLIE SCOTT, and the Minister of Health opened the conference. He defended the Local Government Act, 1929, and spoke of the unsatisfactory features in mental deficiency administration: variations in ascertainment, shortage of institutional accommodation, and lack of supervision and training for those outside institutions.

Mrs. PINSENT said she thought the provisions of the Act would lead to better classification of institutions and patients and so to efficiency, economy, and more humane treatment.

The New Responsibility of Local Authorities.

Mr. B. S. MILLER presented a paper pointing out the opportunities of the present moment and the dangers to be avoided. The Act, he said, removed obsolete divisions and overlapping due to growth and kept the poor out of "watertight compartments." In the interests of the community all mental defectives should be dealt with under the Mental Deficiency Acts, but the work would be too varied and extensive for any one body. The result should be to reduce the amount of what used to be the guardians' work, while retaining the public assistance committee in an advisory capacity. He described the present position and the proposed scheme for Devon. The main thing for the large authorities to do was to concentrate on providing central colonies.

Dr. H. B. BRACKENBURY said that the Act was a very big step forward towards unification. The public health committee, he thought, and not the mental hospitals committee, should be entrusted with mental deficiency work. Probably in time all institutions except the workhouse would come under that committee.

Sir **Leslie Scott** remarked that under the Act mental deficiency would be dealt with, as it ought to be, as a health matter, whereas in the past the poor defective had come under a different authority from the defective who had means.

On Thursday afternoon the chair was taken by Sir **Frederick Willis**, and Dr. A. F. **Tredgold** read a paper on

The Special Investigation Conducted for the Joint Mental Deficiency Committee.

The findings of this report, he said, might be taken as generally applicable to England and Wales; it was the most careful and complete investigation yet made and a valuable scientific document. The most important fact revealed was the number of defectives in the country. The Royal Commission had estimated in 1906 that there were 4·6 defectives per 1000 total population, equivalent to a total of about 150,000 in England and Wales. Dr. E. O. Lewis put the figure at 8 per 1000. This higher incidence was to some extent, but not wholly, due to more complete ascertainment. It was impossible to resist the conclusion that there had been a considerable increase, both absolute and relative to the total population, in the number of defectives since 1906. The figure of 8 per 1000 was still a conservative estimate, and there were more than twice as many defectives as certified insane in the country. The causes of the increase were: (1) The reduction of infant mortality, with the result that the lives of defectives were saved and prolonged. (2) The differential decline in the birth-rate. On the whole mental defect was essentially a family problem, and in that respect stood in close relationship to mental disease in general, several forms of subnormal mental development, chronic pauperism, unemployability, and many varieties of social incompetence and inefficiency. Two sections of the community were contributing more than the average quota to the next generation—the neuropathic and the lowest social stratum. To a large extent these two were one and the same. (3) Migration from country to town, leaving inferior stocks to intermarry in rural areas. The mean average incidence of mental defect was as high as 10·4 in rural districts. (4) The migration of defectives from town to country might play a small part.

The next most important matter dealt with in the report was the employability and employment of defectives. Dr. Lewis had found that only 8 per cent. were unemployable. The majority were capable of useful and remunerative employment, an observation amply confirmed by the experience of all well-run institutions and colonies. It was equally certain that the great majority were not earning, and that if defectives were not suitably trained there was little chance of their obtaining and keeping employment. In fact, 56 per cent. of all adult defectives were being supported entirely or partially by public funds. The number so far ascertained by local authorities was only 1·59 per 1000; obviously defectives could not be dealt with until ascertained. A large number were urgently in need of institutional care which was not available, and it was very doubtful whether neglect to provide it was an economy. A considerable proportion, however, were fit to be at large provided they were properly trained and that suitable employment and adequate supervision and control were assured. The similarity between the conditions in 1906 and in 1928 was striking and tragic; something had been done, but very little.

Finally, Dr. Tredgold spoke most gravely of the mistake of publishing Parts I. and II. of the report without Part III., that dealing with adults: the problem was essentially one and must be considered in its entirety. If mysterious influences were at work to delay or prevent publication this was a most serious thing, and totally at variance with national ideals.

Prof. A. M. **Carr Saunders** commented on the report and said he thought the migration townwards was over-estimated; it might be that extremes of all kinds were better represented in the country than in towns. Interesting results might follow careful observation of the creation of new slums by a certain type of householder in surroundings that gave a fair chance of decent life. Slumdom was quite distinct from poverty. Large towns offered casual labour and the chance of "something turning up" to the shiftless defective, conscious of his failure at steady work. Some indefinite industries in large towns were built up on the employment of the inefficient. The report showed that only 11·6 per cent. of defectives were at present earning enough to keep themselves, but it was doubtful whether employment could be substantially increased. Nowadays employees were carefully selected for industries that formerly took hands from the street when wanted. The financial burden of the defective population was usually underestimated. Borderline cases were under no restraint, and they lived in homes where the birth-rate was high; this might more than counteract the effects of segregation and supervision. The full importance of mental defect was not measured in figures; as society progressed so it became integrated, and each defective became a greater drag on normal persons.

Dr. E. O. **Lewis** pointed out that the amount of mental deficiency was the index of a much bigger problem; for every one defective there were 30 persons mentally subnormal in the "social problem" group.—Miss **Evelyn Fox** emphasised the fact that mental defect was a social problem, a failure of adaptation, and urged the necessity of having enough properly trained social workers to help the defective to adapt.—Mrs. **Hudson** (Leeds) asked if there were not some way to remove the stigma of "silly schools," which hindered ascertainment.—Mrs. **Hodgson** (Eugenics Society) pointed out that the differential birth-rate was causing a very great transference of social class and that the lowest degeneracy might be found in rural slums.—Dr. T. P. **Puddicombe** said that no training or supervision would prevent the defective propagating, and the prevention of reproduction was one of the great problems on which public opinion must be sought.—Mr. W. T. **Wright** advocated segregation.—Dr. F. D. **Turner** thought better ascertainment had a great deal to do with the apparent increase in defectives.—Miss **Dendy** illustrated the difficulty of employing high-grade defectives, who were creatures of impulse, able to develop every faculty save self-control. She said that a family history of some kind of defect could be traced in far more cases than at first appeared. The real criterion of defect was not ability to acquire knowledge, but ability to make use of knowledge.—Dr. **Tredgold**, in reply, said that the prevention of marriage among defectives was very important, though it would not by any means stop the birth of defective children.

On Friday morning the chair was taken by Mr. **Morgan Jones**, M.P., and a discussion took place on the report, with special reference to

Educational and Administrative Problems Concerning Defective and Retarded Children.

Prof. **Cyril Burt** said that the criteria and standards laid down in the report were no more severe than those normally followed, and they showed that there were *roughly 90,000 defective children in the country*. The number in special schools was one-sixth of this and it was impossible to enlarge the special school system to meet the need. Moreover, these 90,000 were but the tail end of a far vaster group of borderline cases, nearly but not quite certifiable. There was no line of cleavage between the dull normal and the feeble-minded. The dull and backward were not deriving proper benefit from ordinary school instruction. The emphasis hitherto had been laid on the defectives, and their claims had overshadowed those of the borderline group, who amounted to 10 per cent. of the whole school population in towns and 15 or 20 per cent. in rural areas. From among these came most of the paupers, criminals, and ne'er-do-weels. Proper provision for the dull and backward was therefore one of the most urgent educational needs of the day. Once they were provided for, the feeble-minded would take their natural place at the tail end of the larger group. The two groups should be dealt with by one scheme. A large proportion of so-called defective children were incompetent pupils *rather than incapable citizens, and were de-certified* when school days were over. It was not fair to stigmatise them by certification and inclusion in a class with low-grade cases who would need permanent supervision. The committee therefore recommended abolition of the certificate; special schools would thus become an organic part of the general system of the public elementary school. Differentiation was more important for the older children. The local education authority would be responsible for all retarded children (except extreme cases) under the age of 11. At 11 there would be a general survey of all children to decide on the best form of post-primary education for each individual. Those who had made no progress in manual and scholastic work would be notified to the M.D. authority, which would thereafter be entirely responsible. Thus children in schools for the retarded would not be brought into contact with low-grade or detrimental children, while special classes would *become an essential part of the general scheme for* post-primary schools. There was urgent need for further research into the efficacy of different methods of instruction, and the way to deal with the temperamental, word-blind, emotional, or excitable child.

Dr. R. H. CROWLEY said that the report enabled us to see unity in much diversity and provided a solid foundation for building. The problem had become static and hampered by its framework. The idea that mental defect was a difference in kind rather than in degree had hindered progress more than any other factor. Defect was important in the light of behaviour and social adaptedness and not in itself. The early years should be allotted to probation and salvage, while at the age of 11 special consideration would be given. Many defective children were not detrimental to others and could derive benefit from a day school junior department. The "ineducable" would be notified to the mental deficiency authority, but it would be the *duty of the education authority* to provide occupation centres for them. Great development was needed in the practice of educational psychology. Boarding-school accommodation should be considered for other children than those requiring permanent institutional care; this would be costly and would require a most careful system of after-care. There should be very adequate classification, as mixing might prove most unfair to high-grade children. The maladjusted, difficult, and unstable child also called for a steady development of educational psychology, and the solution of many social problems was bound up with an effective analysis followed by appropriate action over a long period of years. Failure in behaviour stood out more than failure in intellect. It was upon the mind in its emotional aspects that concentrated thought and action was required.

After some questions had been asked and answered Miss COLLINGWOOD criticised the report as too elastic in its recommendations; the "dull and backward" local authorities would be able to quote it as countenance for continuing to do nothing. In certifying a child as feeble-minded a doctor was using a purely educational diagnosis which did not lie within the medical sphere at all. Certification was little if anything to do with the parents' objection to special schools. They resented dealing with the child by any but the prescribed means, and always would resent it. Mental defect was recognisable soon after 7, *and to delay notification until* 11 was to waste the time of teacher and pupil and to encourage bad habits.

Miss MARTINEAU (President, National Special Schools Union) thought that the same authority should deal with the child right through. Certification, if given up, must be replaced by something equally effective; the word of the educationist would not have the magic spell of medical authority. Parents would object to special schools whatever name was given to them.

Dr. THOMAS BEATON said that the primary trouble was sociological, and doctors had only come into the discussion because they were interested in behaviour problems. Behaviour was the basis of sociological trouble wherever it arose. So long as the child behaved fairly well the doctors were very willing that the teachers should use any device they could to try to help it to grow. No one yet knew the best way, but it was certain that some effort should be made to keep the retarded patient a child for a few more years than the normal individual. There was too great a tendency to treat the child as a unit, whereas everyone was a part of the environment. It was essential to bear in mind what forces were at work in the child's mind, for the reactions it showed depended not only on its own make-up, but also on the pressures which were forcing it. Magistrates tended to rely on probation, which was a serious mistake, for it failed to alter the environment. A primary effort should be made to alter the young delinquent's environment in such a way that—without imposing too great stress—it maintained a standard of conduct which would give him self-respect and satisfy him in his struggle for existence. Pure medicine, individual psychology, and education were all alike useless.

Mr. R. C. MORRISON thought that the most important thing in the report was the new educational unit for retarded children, and pressed for the publication of Part III.—Mr. J. HUDSON (National Special Schools Union) said that it was not sufficient to concentrate dull and backward children into special classes or give them a few special lessons; at least half their time should be spent in handicrafts.—Mr FLAVELL believed that mental defect could be eradicated in a generation if sexual intercourse between defectives was stopped, and Mr. OLIVER pleaded for a single authority.

On Friday afternoon the chair was taken by Prof. T. P. NUNN, and Mr. C. J. R. TIPPER read a paper on an experiment in the

Education of Retarded Children in a Rural County.

In Westmorland, he said, the sparseness of the population was illustrated by the fact that there were 5200 children among 110 schools, and that the average attendance was less than 50 in 69 schools. There was no centre for a day school or class and a residential school was out of the question. The method tried, therefore, was to have one visiting teacher specially trained to assist teachers in devising and adapting methods for these children. Of the 450 retarded children 133 were classified as dull and backward, 39 as mentally defective, and the others were retarded through some removable cause. Many children from remote parts heard little conversation and saw few books at home, and might give a false impression of stupidity at first. Classification was made with the help of the school records, the school medical officer's report, a special report by the head teacher, and the family history, together with Binet-Simon, Burt's, graded reasoning and performance tests. The work now covered 28 children in 14 schools and two large groups for special work. The probable educational or mental age of the child at leaving was forecast and work was so arranged that the child would be doing the maximum of which he was capable by the time he left. (The scheme drawn up might be borrowed by interested teachers.) A good deal depended on the organisation of the class; it was much easier to arrange special work when individual teaching was the rule to a large extent already. The results indicated that dull and backward children could make decided progress in an ordinary elementary school where suitable methods were used and a teacher had guidance from someone who had specially studied the subject. The influence of other children was for the good of the backward child, and he was seldom ill-treated. He was much happier if making progress than if marking time.

Miss K. L. MARSDEN read a paper on the organisation of

Classes for Retarded Children.

In Nottingham, she said, every child of 7 had a simple mental test for classification of his mental age, as normal, subnormal, or possible defective. In 1927 the normal had numbered 4681, the subnormal 438, and the defective 137. The two latter classes were specially tested in greater detail and drafted to the class most suitable—e.g., open-air recovery school, special school, or special classes for probation called "practical classes." Nervous or convalescent children put into a class of 60 might be utterly lost, but in a class where individual or small-group teaching was given would do well and soon be fit for transference to a normal class. Provision was not yet adequate for the number of "retarded" children in our schools, and until they were properly taught we were wasting their limited mental power and also the ability of children who could get on faster if not taught together with the slow. The classes for the dull and backward were as much a part of the school as any other, and the children mixed with others at play and in singing, needlework, and other classes. Records were kept of each member of the practical class, and any marked ability was encouraged. About 10 per cent. returned to normal classes, but the numbers varied considerably.

Mgr. T. A. NEWSOME read a paper on experiments in the

Education and Training of Retarded Children.

His work, he said, was based on 12 years' experience of mentally defective boys at Besford Court. The small institution must not be conducted on the "menagerie" principle, but must receive only patients whose mental defect falls within a certain definite range. For low-grade defectives who would spend their lives in a colony, education in the three R's was waste of labour and money. For higher-grade patients, to whom it was proposed to teach a useful trade for eventual return to the community, the teaching of the three R's absorbed most of the time needed for learning the trade. The junior department at Besford Court (for boys aged 7–12) had therefore been transformed into a Montessori school, with great success. The increased enthusiasm was marked and careful observation of mental ratios showed that the final results of this system were really excellent. The achievement ratio of boys of the Montessori department had been raised from 79 to 98 per cent.—i.e., their actual educational attainment was 98 per cent. of their native ability. The salient feature of the Besford Court system was that reading, writing, and arithmetic were merely the foundation for the real training. However proficient in these subjects a child might be rendered by special methods he was still defective in the true sense of the word, and his defect must be compensated by intensive training in some craft. In a custodial home shoemaker's and tailor's shops and gardening departments were run by experts with mentally defective assistants, but it was extremely debatable whether these occupations trained defectives to earn their living later on in these trades. Shoes and garments to-day were factory-made, and tailoring was an unhealthy trade for defectives, who were not, physiologically, healthy people. In the custodial home economy of working and healthy, happy employment were the first considerations, but the special school had a totally different aim. The most gratifying results had been obtained at Besford Court in training defective boys to be as proficient at certain crafts as normal workmen. The trades, in the order of the mental ratio required,
to [illegible] painting (lowest), rural handicrafts, gardening,
serious [illegible] bricklaying, and skilled carpentry. The
ideals. [illegible] was of losing the individual in the
Prof. A. M. [illegible]tient must have special study and
[illegible]port and said h[illegible] special treatment. One faculty might become exhausted and another might suddenly begin to develop.

Character defects might be innate or acquired, and the two types needed quite different treatment. The cause of bad conduct must be ascertained in every case, and the child must be regarded as a patient and not a culprit. The residential school was to the child-guidance clinic as a well-conducted hospital to the specialist's consulting-room, and should be a research centre with detailed records and opportunities for conference. Mgr. Newsome described the method by which cases were studied and discussed at Besford Court. It was almost invariably the rule that conduct disorders showed their first signs of improvement in the report of the manual instructor, revealing the close association of conduct disorder with inferiority complex. The other important association with conduct disorders was physical ill-health. Open-air life and ultra-violet light had proved useful, but a number of cases seemed likely only to be understood by a study of endocrine imbalance.

Questions and discussion followed.

MEDICO-LEGAL SOCIETY.

AT a meeting of this Society held on April 25th the chair was taken by the President, Sir WILLIAM WILLCOX, and Lord RIDDELL read a paper on

STERILISATION OF THE UNFIT.

He pointed out that there were 138,293 notified insane persons and 61,522 defectives in England and Wales in 1927 and that 3047 of the former had been discharged "relieved, but not recovered," while on an average 600 were allowed out every day on parole in an unstable mental condition. The institutional accommodation for mental defectives fell short of requirements by some 18,038. He quoted examples, given by the Board of Control and other authorities, of the families produced and the crimes committed by defectives. The Board deprecated the marriage of defectives, but refrained from stating that the sexual instinct was very powerful among these people and that they would go to any lengths to give expression to it, being oblivious of results or sanctions and very prolific. The colonies recommended by the Board to fulfil their policy of segregation would cost enormous sums; could the community afford to spend 20 millions on a section of the population of the worst type? The abnormal citizen already received far more care and attention than the normal one. No one suggested that sterilisation was a complete solution of the problem, but it would reduce the necessity for segregation and consequently the expense. The Board said that "the life of the colonists approximated to village life"; it would be interesting to know if the authorities had discovered methods of damping down the normal sexual impulses of the colonists. The Board failed to give due prominence to the strength and permanence of the sexual instinct in certain classes of defectives. The propagation of undesirables was a national menace and the condemnation of high-grade defectives to celibacy was unjustifiably cruel. They produced bad stock and made bad parents, but sterilisation would cover both these objections. The existing system was incoherent and illogical; on the one hand the Board were demanding more institutions, and on the other their policy was to return as many lunatics and defectives to the outside world as possible, thus providing opportunities for them to breed more defectives and more criminals. Sterilisation would endow the parole-discharge-and-licence policy with more freedom and more safety to the community and would tend to reduce the multiplication of the mentally diseased. The operation would only be performed with the consent of the patient, or—if incapable of consent—of the parents or guardians, and would increase rather than restrict the liberty of the individual and of his or her mate. Individual liberty was constantly being restricted for the safety of the community, as in vaccination and segregation for infectious disease. Sterilisation would not increase promiscuity and venereal disease; the sterilised would still be under supervision and the operation would leave their inhibitions—if any—unaffected. The operations were not dangerous and did not affect the sexual functions. In California 3232 vasectomies and 2588 salpingectomies had caused only three deaths—two from the anæsthetic and one from premature removal of dressings by the patient. The results had been highly satisfactory in California and compulsory sterilisation had now been prescribed by law in one of the Swiss cantons and in Alberta, Canada. At present the interest and happiness of the individual patient were put before the general interest of the community; the whole subject required statesmanlike attention.

Discussion.

A letter from Lord **Atkin** was read, suggesting discussion of the following points: selection of patients and who should make it; what consents, if any, were to be required; whether there should be any judicial or other appeal; whether incurable cases only should be sterilised; at what age the operation should be performed; and whether the patient must show some propensity to bear or beget children.

Dr. F. J. **McCann** said that sterilisation was of little or no value; his objections were that it did not affect the source of supply, that it did not make the unfit clean, sober, righteous, or worthy, that it returned to society sterilised persons liable to transmit venereal disease, and that the sterilised would still require supervision. Sterilisation was very attractive to those who had a superficial knowledge of the problem. Half the defectives born were begotten by parents who were not defective and, if alcohol, syphilis, and other germ-plasm poisons were eradicated. more would be done for the race than by any other means. Nature had her own way of eliminating the unfit; defectiveness appeared earlier in each generation, so that insanity became imbecility in three or four generations, and there was a high percentage of developmental defect in aborted ova. It was exceptional for the feeble-minded to marry into healthy stocks. The surgical results claimed by enthusiasts were hard to justify, and he did not believe that no change in testis or ovary followed sterilisation. The subject of heredity was so little understood at present that no one could decide which cases were suitable for sterilisation. Where segregation was permanent and supervision close all the advantages claimed for sterilisation were obtained without it.

Dr. R. A. **Gibbons** said that sterilisation offered an effective means of preventing the birth of an enormous number of defective children, 70–80 per cent. of whom owed their condition to neuropathic heredity. Most people agreed that nothing could be better than thorough segregation, but it was quite impossible to segregate all our defectives. Sterilisation was complementary and not alternative to segregation. Paul Popenoe in California had found no evidence whatever that sterilisation played a part in increasing sexual delinquency or venereal disease. In 21 years 23 States had adopted sterilisation laws. After discussing the legal implications of a sterilising operation, Dr. Gibbons urged the importance of preventing the marriage of defectives. When there was no hope of improvement sterilisation ought to be compulsory, like vaccination, but no operation should be performed without the consent of the Board of Control. If the consent of the patient or his parents were required it would be a long time before advance was made.

Earl **Russell** was appalled at the large sums being spent on these comparatively useless members of the community while the healthy and useful were in great need. It was worth while, he said, to pay some attention to the healthy as well as to the diseased, and employment and proper housing were quite as important as the treatment of defectives. Bricks and mortar should be provided for those who did not yet and might never require institutional treatment. Dr. McCann had said that Nature eliminated the mentally unfit in time, but could not we do something to help Nature? Voluntary sterilisation would not do much; even parental consent would not be easy to get if the parents were usually unstable people. If supervision were to prevent sexual intercourse it would have to be as close as in an institution. Too much attention was paid to the sick and too little to the healthy; we should encourage the breeding of healthy stock. Sterilisation of the obvious case was a very small infringement of personal liberty.

Dr. **Nathan Raw** said that the increase of insanity called for preventive measures. Segregation would be satisfactory, if it were possible, but sterilisation was the only feasible method for certain cases. It should be carefully safeguarded and the consent of the guardians or of the Board of Control or some authority should be required. It was the only scientific remedy we could apply to redress this great burden on the State. At first it should be advocated only for the weak-minded boys and girls who reproduced freely, without really being responsible.

Dr. T. B. **Hyslop** reviewed his experience and thought the progress of sterilisation had been delayed by fetish-worship of the liberty of the subject. He thought consent of both patient and relatives ought to be obtained to guard the operator against subsequent legal action.

Dr. **Temple Gray** was convinced that Nature knew quite well how to look after evolution without the intervention of Boards of Control. It was not true that defectives were disastrously prolific; while their birth-rate might be a little higher than that of others, their death-rate was five times the normal. "Consent" from a mental defective was a contradiction in terms.

Lord **Riddell**, in reply, contrasted the economy talk with the enormous expenditure proposed by the experts in mental defect; if the nation was not going to spend this money, what was it going to do? Were we going to sit down quietly and let the race be poisoned and crippled in the markets of the world? Was it right, with housing conditions what they were, to contemplate spending 20 millions on a class of people who would never be any use to the nation, and to keep mental defectives at 42*s*. a week when normal children were being taught in classes of 60 and kept under utterly unsuitable conditions?

MANCHESTER MEDICAL SOCIETY.

At a meeting of this Society, held on April 3rd at the Manchester University, with Dr. R. W. **Marsden**, President of the Society, in the chair, Dr. **Charles H. Melland** read a paper on the

Treatment of Pernicious Anæmia by Liver.

Dr. **Melland** gave an epitome of his experience of the treatment of some 40 cases of pernicious anæmia by liver in the last two years. With certain exceptions the results were almost uniformly good, but it is too soon yet to say definitely how much better than the older methods of treatment. These older methods, if effectively handled, were undoubtedly very successful in many cases, and Dr. Melland gave instances of patients who had lived for 17, 9, 8 years, and so on, with more or less complete freedom from symptoms over long periods, as the result of treatment by such methods. In order to achieve such results, however, very great care in carrying out the details of the treatment was called for, and it was often difficult to secure this careful attention, with the result that relapse and early death was only too common. Although it was too soon as yet to draw final conclusions, Dr. Melland was of opinion that the addition of the liver treatment to the older methods was undoubtedly of the greatest value, the results were attained more speedily, the recovery was more complete, the improvement was maintained more easily, and with much less tendency to relapse.

NORTH OF ENGLAND GYNÆCOLOGICAL AND OBSTETRICAL SOCIETY.

AT a meeting of this Society held at Liverpool on March 15th, with Dr. G. W. FITZGERALD, the President, in the chair, a paper on the

Pathology of Cervicitis

was read by Dr. K. V. BAILEY. He had examined 850 specimens of the cervix uteri, he said, with a twofold object—namely, to ascertain the precise pathology of the so-called cervical erosion and with a thorough knowledge of this pathology as a basis, to inquire into the problem of the inception of cervical cancer. The present paper dealt with the pathology of cervicitis, of which he distinguished two types: (1) The relatively unimportant and rare condition of congenital erosion seen in the nulliparous and presumably non-infected cervix. Reel had described this condition and thought it was due to anomalous growth of the mucous membrane lining the cervical canal. In the speaker's series this type showed definite inflammatory reaction, and therefore there was no reason to differentiate it from the inflammatory type. (2) The large group of inflammatory erosions. Dr. Bailey believed that the life-history of this condition fell into four distinct stages.

Stage 1.—The primary effects of irritation. This was characterised microscopically by the stripping off bodily of the squamous epithelium at the level of its lowermost cells by large and small blood cells and the inflammatory exudate as a whole.

Stage 2.—Epithelial reaction to inflammatory irritation. Proliferation and repair. Microscopically the evidences of inflammatory reaction are definitely lessened. The surface exudate is less and intimately associated with the new surface epithelial covering which is identical with and derived from the columnar epithelium lining the cervical canal.

Stage 3.—Replacement of columnar by squamous epithelium on the surface of the affected area. In this stage the squamous epithelium grows over the affected area by new cells growing from the basal layer of the nearest unaffected squamous epithelium upwards towards the adjacent columnar epithelial surface and lifting the single layer upwards lever fashion, thereby gradually replacing it. In this stage tissues immediately beneath the columnar epithelial layers are greatly rarefied.

Stage 4.—The stage of ultimate healing. This stage is characterised by the presence of dilated gland spaces situated beneath the new covering—the result of mechanical blocking of their ducts by the squamous cells. Pseudo-malignant appearances result from irregular downgrowths of squamous cells, especially in connexion with the mouths of dilated gland spaces.

Dr. Bailey had found 42 examples in his series of a true ulcerative erosion of the cervix which was pathologically akin to the condition already described. The affected area was depressed with overhanging epithelial edges in immediate contact and a smooth granular depressed base coated with chronic exudative material. It was a condition relatively common in association with the damaged and hypertrophied cervix usually removed during the operation for uterine prolapse. He suggested that from the pathological standpoint the term "erosion" was erroneous, and he proposed that the group of cases known as erosion (papillary, follicular, &c.) should be called "peri-oricular cervicitis," that true ulceration of the cervix should be termed "ulcerative cervicitis," and that infection limited to the cervical glands should be called "glandular cervicitis."

The Cæsarean Scar.

Prof. W. BLAIR BELL showed a specimen of a uterus with scar of a Cæsarean wound. The specimen was obtained at the post-mortem examination of a patient who died a few hours after an emergency Cæsarean section. It clearly demonstrated, Prof. Blair Bell said, the result of the procedure he had advocated and described.[1] The strong, heaped, muscular scar, the absence of catgut on the peritoneal and mucosal surfaces, and the complete apposition of the parts were revealed. The question of rupture of the Cæsarean scar had often been discussed and cases had been admitted to the Royal Infirmary in the last few years of both rupture and impending rupture. Prof. Blair Bell knew of no case of his own in which such conditions had supervened. It was, of course, obvious that infection in a scar might be responsible for imperfect union, but he was convinced that the method of suture was of paramount importance whether in clean or infected scars. An unpunctured, accurately apposed mucosa, and wide muscular union, as shown in the specimen, must be of importance. Furthermore, the absence of suture material projecting on the peritoneal surface removed or reduced a constant source of omental and intestinal adhesions.

The PRESIDENT stressed the necessity for accurate opposition of the edges of the scar. He said that his method of suture was similar to that of Prof. Blair Bell except that he did not use the mattress suture. A patient of his had had a rise of temperature after an emergency Cæsarean section. She did not report on her next pregnancy, but delivered herself normally. In the third pregnancy the scar ruptured.

Miss FRANCES IVENS said that she avoided the endometrium in sewing up her scars and used two layers of catgut, the last layer taking in a large bit of uterine muscle. She had had an opportunity of studying one of her scars five weeks after Cæsarean section. The patient had fibroids and as conditions were not suitable for hysterectomy at the time of the Cæsarean section the uterus was removed five weeks later. The uterus showed that the scar was thicker than the rest of the uterine wall and microscopically its track could be traced by a line of giant cells.

Prof. BLAIR BELL replied that a badly sewn wound was more likely to rupture afterwards even in the absence of infection.

A Case of Ovarian Tumour.

Prof. W. BLAIR BELL also showed two specimens, one of which was from a case of ruptured papillary ovarian tumour.

The patient was a single woman aged 35. Eighteen months previously the left ovary had been removed by Dr. Leith Murray, being the seat of a growth similar to that now described. It appeared malignant macroscopically, but on section was regarded as innocent. Two pints of fluid (not blood-stained) were evacuated from the abdomen, due to rupture of the upper pole of the tumour before operation.

In January, 1929, she was admitted to a medical ward with abdominal swelling, dyspnœa on exertion, swelling of the ankles, and loss of weight. One and a half pints of fluid were aspirated from the right pleural cavity, but there was no evidence of tuberculous disease. A week later eight pints of fluid were withdrawn from the abdomen by paracentesis. Eleven days later laparotomy was done under spinal anæsthesia and two pints of thick, straw-coloured fluid were evacuated. The growth of the right ovary was slightly adherent posteriorly and the uterus was displaced to the left. It was not removed on account of the condition of the patient. There were bands running over the growth which had the appearance of adherent intestine and omentum.

The growth was also cystic in several places, but its general appearance was that of a friable, soft, solid malignant tumour. Histologically it was a papillary adenoma.

ABERDEEN MEDICO-CHIRURGICAL SOCIETY.

REPORTS OF CASES.

A MEETING of this Society was held on April 4th, with Prof. ALEXANDER LOW, the President, in the chair.

Dr. WILLIAM BROWN reported two cases of Erythrœdema Polyneuritis (Pink Disease). They illustrated, he said, the following points: change in temperament and expression; swelling of the face and the high colour of cheeks and nose; the presence of stomatitis; desquamation of hands and feet, with tenderness; and the characteristic attitude in bed.

---

[1] Jour. Obst. and Gyn. Brit. Emp., 1925, xxxii., 727.

The two chief signs of the disease were the look of "misery" and the colour of the hands and feet. Both cases had been admitted with a history of change of temperament and of depraved appetite, sweating, redness and coldness of extremities. One case was in hospital for four months and the other for two months. Both were treated with a diet rich in vitamin B in addition to general tonic treatment. Marmite was given in large doses. One case improved rapidly on receiving ultra-violet rays. Calcium was given to both cases. Dr. Brown mentioned the similarity, in some respects, between this disease and beri-beri and pellagra, especially the latter.

Dr. J. F. CHRISTIE described a case of ecthyma which, he said, was really a deeper form of streptococcal impetigo, although sometimes a deep tuberculous focus was concerned in the ætiology. The children were usually in poor condition and the buttocks, thighs, and legs were most commonly affected. The best applications were either a 1 per cent. solution of silver nitrate or 1/2000 solution of mercuric chloride. In the present case the child made a good recovery, but returned to hospital three weeks later with broncho-pneumonia. Six weeks after convalescence the patient was readmitted and died of generalised tuberculosis.

Dr. Christie also described a case of pemphigus vulgaris in a male child aged 3 years. It was of note that the infant had suffered from chicken-pox three months previously.

Typical bullæ appeared on the arms, backs of the hands, genitals, and adjacent parts of the thighs. The bullæ came out in crops without much rise in temperature, and with no itching. A polymorphonuclear leucocytosis was present with 7 per cent. eosinophils. Condy baths were prescribed and an ointment containing hydrarg. ammon. and ichthyol was applied. Increasing drop doses of Fowler's solution were given by mouth. There was no improvement after a month and quinine sulphate was then given. Later, on withdrawing serum from what appeared a sterile bulla, an almost pure culture of a hæmolytic streptococcus was found. Antistreptococcal serum was then injected, in all five doses at seven days' intervals.

Bullæ still continued to form with slight rises in temperature, but at the end of five weeks the child was considerably better and left the hospital with no signs of any skin affection.

Dr. H. ROSS SOUPER described the appearances and course of a case of acute suppurative frontal sinusitis in a girl aged 10.

There was marked swelling of both eyelids and bilateral proptosis and a fluctuating swelling was present in the mid-line of the forehead. A skiagram showed well-marked opacity of both frontal sinuses with necrosis of the supraorbital ridges. At operation pus was found superficial to the frontal bone, both frontal sinuses were filled with pus, and abscess cavities extended through the roof of both orbits. Part of the frontal bone was necrosed and removal exposed the dura mater. Free drainage was established, but the patient died next day. A staphylococcus was isolated from the pus.

Dr. Souper also described a case of lateral and cavernous sinus thrombosis in a boy aged 3.

On admission the child had a temperature of 100·2° F. and slight left otorrhœa. There were no definite external signs of mastoiditis. Two days later œdema of the left eyelid appeared, followed by œdema of the right eyelid the next day. The temperature rose to 103° and a polymorphonuclear leucocytosis of 43,000 was present. At operation necrosis of the mastoid cells was found. The lateral sinus was found to be covered with granulations and contained a clot which was removed. The patient received antistreptococcal serum, but died the following day.

Dr. Souper discussed a series of 22 cases of tuberculous mastoiditis in children. The condition occurred between the first and third year of life, was insidious in onset, and the facial nerve was often involved. The discharge from the ear was curdy and flaky and multiple perforations were often present; early glandular involvement occurred and the pre-auricular glands were especially implicated.

Dr. JOHN CRAIG showed several cases including one of cœliac disease in a girl of 6½ years, who had a history of diarrhœa for several years with the passage of large, loose, pultaceous stools. She had been fed as an infant continuously on a proprietary food. The appearances of the case were classical—infantilism, large abdomen, thin flabby limbs, wasted buttocks, with the usual quaint introspective mentality and squeaky voice. Skiagrams showed many transverse striations of the ends of the long bones.

Reviews and Notices of Books.

THE DIAGNOSIS AND TREATMENT OF GONORRHŒA.

Diagnostic et Traitement de la Blennorragie. By Dr. JULES JANET. Paris: Masson et Cie. 1929. Pp. 536. Fr.60.

A COMPREHENSIVE volume on gonorrhœa from the pen of Dr. Janet, one of the pioneers of treatment by urethro-vesical irrigation whose experience of this disease is unrivalled, has long been eagerly anticipated.

By far the most valuable feature of the volume is the wealth of practical detail concerning the technique of treatment by irrigation. The danger of injury to the delicate urethral mucous membrane in the acute stages of the disease by instrumental treatment or by irrigation at an unduly high pressure is carefully considered. Dr. Janet is emphatic in stating that during urethro-vesical irrigation the relaxation of the urethral sphincter should be the result of gentle and skilled persuasion and not of force; the maximum head of fluid used should never exceed a metre. The retention of potassium permanganate solution in the bladder after irrigation is strongly condemned on account of the precipitation of insoluble manganese dioxide which takes place. With regard to the controversial question of when irrigation into the bladder should be commenced, Dr. Janet's practice is to confine irrigation to the anterior urethra only during the early stages; when there is evidence of infection in the posterior urethra, and not until then, urethro-vesical irrigation is advised. Irrigation is continued even in the presence of acute prostatitis, although the concentration of the solutions used is reduced. Amongst the various tests of cure, which are fully discussed, considerable importance is attached to the examination and cultivation of the semen; the author has not, however, found this method to yield positive results in chronic infections in the high proportions quoted by many other authorities. The instrumental treatment of chronic gonorrhœa in the male receives but a brief description; the urethroscope is considered of value only in unusual cases. A particularly interesting and well-illustrated chapter describes the treatment of infection in the various types of para-urethral ducts. The section on the diagnosis and treatment of gonorrhœa in women conforms closely to generally accepted practice; the author's outlook on the likelihood of cure in chronic infections is pessimistic. The secondary infections of the female genital tract are believed to be quite as dangerous as the primary gonococcal infection and never to undergo spontaneous cure, whereas in males this termination after a time is not infrequent. Chronic gonococcal infections are held to be the cause of three-quarters of the gynæcological lesions in women.

This volume will be of value to all practitioners who treat gonorrhœa by irrigation.

EPILEPSY.

By WILLIAM G. LENNOX, M.D., Research Fellow in Neuropathology, Harvard Medical School; and STANLEY COBB, M.D., Bullard Professor of Neuropathology, Harvard Medical School. London: Baillière, Tindall and Cox. 1928. Pp. 197. 16s.

WHATEVER be the exact or appropriate connotation to apply to the term epilepsy, and whether it is a disease or a symptom, little advance has been made in knowledge of the subject of recent years, notwithstanding our claims that we know a great deal more than the preceding generation. It is a reproach to medicine that this should be true, for epilepsy is common, often distressing, turns up in unexpected quarters, and its prognosis is always uncertain. This being the case, a survey of the precise situation and of the lines of approach is sure to be useful. This has been provided by Dr. Lennox and Dr. Cobb, of the Harvard Medical School; their monograph is proof not only of their wide acquaintance with an enormous literature but also of their selective skill and critical acumen. They have wisely eschewed controversy and have been content to point out contradictions without entering the lists themselves in a challenging fashion; yet the reader will soon appreciate the fact that when they adopt any particular attitude of clinical or pathogenic interpretation they have reason on their side.

Theories of the actual neural mechanisms involved in convulsive seizures are epitomised, and such evidence as pathology affords is fully examined. In proper sequence the action of possible factors outside the nervous system itself is carefully set out; these factors range from circulatory and blood states to the endocrines. Particular attention is concentrated on the long series of biochemical investigations that have been applied to epileptic problems; all sorts of metabolic researches, concerned with proteins, fats, carbohydrates, with acid-base relationships, with alkalosis and acidosis, have been scrutinised in the hunt for promising lines of advance. Only a minor section of the monograph deals with the more practical aspects of prophylaxis and treatment; yet after all this is only as it should be, since treatment has never yet passed the empirical stage. A bibliography occupying some 30 pages contains, we estimate, some 700 references.

All that is known about epilepsy is here, at least all that is worth knowing. The book furnishes the serious student of the subject that *mise au point* which, we believe, may be a stepping-off place for further exploration.

NOSE, THROAT, AND EAR.

The Care of the Nose, Throat, and Ear. Second edition. By W. STUART-LOW, F.R.C.S. Eng., Consulting Surgeon to the Central London Throat, Nose, and Ear Hospital. London: Baillière, Tindall and Cox. 1929. Pp. 90. 5s.

THE second edition of this book includes a short account of the ear. It has been written for the general public, and those of the laity who desire a smattering of knowledge of the nose, throat, and ear, and their diseases will find what they want in its pages. The author of a work of this kind is necessarily dogmatic and must find it difficult to avoid occasional exaggeration. Certain statements may be quoted which err in this direction, such as "if the nose is blown properly when a cold in the head is in its early stages its development can be stopped." Of hay-fever the author states that "the nose is at fault in all such cases, and should have skilled examination and attention to effect a cure, which can be brought about in all instances." He also says that it is now recognised that a large majority, if not all cases of asthma, are dependent upon some nasal obstruction or disturbing condition of the nasal cavity. Such over-statements are misleading.

Notes on Otorrhœa, with Especial Reference to the Use of Zinc Ionisation in the Treatment of Selected Cases. By A. R. FRIEL, M.A., M.D. (Univ. Dub.), F.R.C.S.I., Assistant Aurist, School Medical Service, London County Council. Bristol: John Wright and Sons. 1929. Pp. 88. 6s.

THIS is a careful and lucid account of the treatment of chronic aural suppuration by zinc ionisation given by a well-known exponent of the method. The first part of the book is occupied by a clear elementary statement of the physics of ionisation with an account some experiments illustrating the action of zinc ionisation on albumin and bacteria. The apparatus employed might well have been described at greater length. The most important section of the book is that concerned with the technique of treatment by ionisation as applied to chronic otorrhœa. Here a notable feature is the attention which Dr. Friel pays to the appearance of the tympanum and to the details of treatment. There is little doubt that many cases of suppuration would be cured by the careful syringing and instillation of zinc sulphate, which is preliminary to this treatment, without the ionisation, but the use of ionisation makes the cure much quicker, and this renders the method particularly valuable in school clinics. Ionisation is successful only if undertaken with scrupulous care, and this exposition will be of value to all who make use of this form of treatment.

FORENSIC MEDICINE AND TOXICOLOGY.

By the late Dr. FRED J. SMITH. Third edition. Edited by Dr. GEORGE JONES. London: H. K. Lewis and Co., Ltd. 1929. Pp. xx. + 440. 10s.

THIS book makes no pretence to being an exhaustive treatise on legal medicine, but was compiled as an epitome of the lectures given at the London Hospital Medical School, with which institution the late author was and the editor has long been associated. Into its 440 pages has been collected a surprising amount of material of the greatest use to students preparing for examinations.

The book has been carefully revised by Dr. George Jones, who has interpolated a considerable amount of new matter. The whole range of forensic medicine is covered, though lack of space has prevented sometimes an adequate presentation. Many of the descriptions are doubtless amplified in the lecture and post-mortem theatres of the London Hospital. In future editions more of the original text might be eliminated, and the space thus obtained utilised to expand the more technical side of the teaching.

THE CHILD OF CIRCUMSTANCE.

By ALBERT WILSON, M.D. Edin., late President of the Royal Medical Society of Edinburgh. London: John Bale, Sons and Danielsson. 1928. Pp. 420. 15s.

THIS book occupied the energies and interest of the late Dr. Albert Wilson almost up to the day of his death. It covers the varied aspects of criminology, is rich in personal experience, and marked by definite opinions upon such matters as capital punishment and the lash, both of which the author would retain though substituting the lethal chamber for our cruder method of carrying out the former. Yet his humanity and his understanding of the wrongdoer find expression throughout, and he reminds us again and again of the good work done by the Quakers and the Salvation Army in the direction of helping the criminal, both by alleviating unnecessary suffering and aiding reform. The penal systems of Europe and America are described in the light of modern knowledge, and this part of the book is itself a mine of information.

It is a commonplace of scientific history and not a reproach to the writer that he has not readily assimilated some of the new ideas now freely accepted, and it must be admitted that his criticisms of the psychological teachings of McDougall and Freud—which he wrongly treats as identical—belong to the past. But his book is the product of a vigorous and humane personality ripened by long experience, and its varied contents will interest the reader, whether he be a layman or a doctor.

IN the review of the second edition of "Regional Anæsthesia." by Gaston Labat, M.D. (W. B. Saunders), last week the number of pages should have been 567, and the price 35s.

Parke, Davis & Co.

LIVER EXTRACT

THE LIVER EXTRACT offered by Parke, Davis & Co., for use in the treatment of pernicious anæmia, is prepared by a method that has been shown to produce an exceedingly active product. It is supplied in vials each containing the extract from 100 grammes (nearly four ounces) of fresh liver, the contents of three or more vials being taken daily.

The P., D. & Co. Liver Extract is a palatable preparation with a pleasant salty taste, and it may be taken sprinkled over potatoes, meat or bread. Its miscibility with water, milk, soup, orange or lemon juice and other liquid foods also suggests other acceptable modes of administration.

Supplied in packages of 24 vials.
Further details will be
furnished on request.

Parke, Davis & Company,
50 Beak Street,
LONDON, W.1.

LEWIS'S BOOKS FOR STUDENTS

JUST PUBLISHED. EIGHTH Edition. With 2 Plates and 91 other Illustrations. Demy 8vo. 21s. net; postage 9d.

HYGIENE AND PUBLIC HEALTH

(PARKES AND KENWOOD).

Revised by **HENRY R. KENWOOD**, C.M.G., M.B., F.R.S.(Edin.), D.P.H.(Lond.), Emeritus Professor of Hygiene and Public Health in the University of London, &c.; and **HAROLD KERR**, O.B.E., M.A.(Dunelm), M.D.(Edin.), D.P.H.(Camb.), Professor of Hygiene and Public Health in the University of Durham, &c.

"The work has been brought up to date, and will continue to be the 'guide, philosopher and friend' of all who wish to learn the principles and practice of preventive medicine."—THE MEDICAL OFFICER.

RECENTLY PUBLISHED. With Illustrations. Demy 8vo. 12s. 6d. net; postage 9d.

ELEMENTARY MEDICINE IN TERMS OF PHYSIOLOGY

AN INTRODUCTION TO CLINICAL WORK.

By **D. W. CARMALT JONES**, M.A., M.D. Oxon., F.R.C.P. Lond., Professor of Systematic Medicine, University of Otago, New Zealand; Physician, Dunedin Hospital, New Zealand; Consulting Physician, Westminster Hospital, &c.

"It is a book that would benefit not only junior and senior students alike, but many who are still students although qualified."—MANCHESTER UNIVERSITY MEDICAL SCHOOL GAZETTE.

With 13 Plates and 30 other Illustrations. Demy 8vo. 12s. 6d. net; postage 6d.

A SHORTER SURGERY

A Practical Manual for Senior Students.

By **R. J. McNEILL LOVE**, M.B., M.S.Lond., F.R.C.S.Eng., First Surgical Assistant, London Hospital, &c.

". . . a great deal of sound information clearly imparted."
—BRITISH JOURNAL OF SURGERY.

NOW READY. With 176 Illustrations contained in 52 Plates. Crown 4to. 7s. 6d. net; postage 6d.

ELEMENTARY PATHOLOGICAL HISTOLOGY

By **W. G. BARNARD**, M.R.C.S.Eng., Pathologist, University College Hospital.

"Dr. Barnard is to be congratulated on a book which will certainly be deservedly popular with students. It is beautifully produced and inexpensive."—THE LANCET.

With 273 Illustrations. Crown 8vo. 12s. 6d. net; postage 6d.

MINOR SURGERY

By **LIONEL R. FIFIELD**, F.R.C.S. Eng., Surgical First Assistant and Registrar, London Hospital; Demonstrator of Anatomy and late Demonstrator of Minor Surgery, London Hospital.

". . . absolutely up to date . . . can be confidently recommended in the teaching, study and practice of minor surgery."
—BRITISH JOURNAL OF SURGERY.

BY THE SAME AUTHOR.

With many Illustrations, in Plates and the Text. Crown 8vo. 9s. net; postage 5d.

INFECTIONS OF THE HAND

"We can heartily recommend the book to students, house surgeons and practitioners."—QUEEN'S MEDICAL MAGAZINE.

FIFTH Edition. Revised and Enlarged With 11 Plates (6 Coloured) and 76 other Illustrations. Demy 8vo. 21s. net; postage 9d.

MIND AND ITS DISORDERS

A Text-Book for Students and Practitioners.

By **W. H. B. STODDART**, M.D. Lond., F.R.C.P., Physician for Mental Diseases, St. Thomas's Hospital; Lecturer on Mental Diseases, St. Thomas's Hospital Medical School; Late Examiner in Psychology and Mental Disease to the University of London, &c. [*Lewis's Practical Series.*

". . . students, practitioners, and specialists will all find much of value in this eminently readable volume."
—THE PRACTITIONER.

With 130 Illustrations Demy 8vo. 18s. net; postage 9d.

A SHORTER ANATOMY

WITH PRACTICAL APPLICATIONS.

By **E. WOLFF**, M.B., B.S.(Lond.), F.R.C.S.(Eng.), Demonstrator of Anatomy, University College, London; Chief Clinical Assistant, Moorfields Ophthalmic Hospital; Author of "ANATOMY FOR ARTISTS," &c.

". . . An eminently readable book . . . gives accurate information in a simple and lucid way. The illustrations are clear."
—THE LANCET.

SIXTH Edition. With New Illustrations (mostly in Colour). Demy 8vo. 7s. 6d. net; postage 5d.

LANDMARKS AND SURFACE-MARKINGS OF THE HUMAN BODY

By **L. BATHE RAWLING**, M.B., B.C. Cantab., F.R.C.S. Eng., Surgeon to St. Bartholomew's Hospital, &c.

"This edition will doubtless be as popular as its predecessors, both with students and surgeons."—BRITISH MEDICAL JOURNAL.

SECOND Edition. Revised, with 2 Plates (1 Coloured). Crown 4to. 7s. 6d. net; postage 6d.

PRACTICAL HISTOLOGY FOR MEDICAL STUDENTS

By **D. T. HARRIS**, B.Sc., M.B., B.S., Assistant Professor of Physiology, Institute of Physiology, University College, London, &c.

". . . to be recommended. . . . The book is a really useful one and goes far towards supplying a long-felt need."
—ST. BART'S HOSPITAL JOURNAL.

EIGHTH Edition. With 6 Plates and 72 other Illustrations in the Text. Demy 8vo. 12s. 6d. net; postage 6d.

PUBLIC HEALTH LABORATORY WORK

(Chemistry).

By **H. R. KENWOOD**, C.M.G., M.B., F.R.S. Edin., D.P.H., Emeritus Professor of Hygiene in the University of London, &c.
[*Lewis's Practical Series.*

"Probably no other book in laboratory technique has had so large and appreciative an audience."—THE MEDICAL OFFICER.

NOW READY. TENTH Edition. F'cap 8vo. 6s. 6d. net; postage 4d.

A HANDBOOK OF SANITARY LAW

For the Use of Candidates for Public Health Qualifications.

By **B. BURNETT HAM**, M.D., M.R.C.S., D.P.H. Camb., Fellow of the Royal Sanitary Institute; Fellow of the Royal Society of Tropical Medicine and Hygiene, &c.

THE LANCET.

LONDON: SATURDAY, MAY 4, 1929.

THE COSTLINESS OF RADIUM.

THE National Radium Fund was opened on Monday last in response to a letter in the *Times* signed by the heads of the medical profession and by certain distinguished laymen closely connected with institutions where cancer is being treated with radium. The letter, which we print in full on p. 937, indicates how great and urgent is the need, and appeals for £150,000 to purchase radium on a scale adequate for the present and the near future. For every £1 subscribed the Government will grant £1 up to a limit of £100,000, bringing up the total sum available to £250,000. The Fund is regarded as an impressive way of commemorating the thankfulness felt by the Nation for the KING's convalescence after his dangerous illness. At the same time was announced an anonymous donation of 100,000 guineas to King Edward's Hospital Fund for London as a nucleus for a large thank-offering fund which is also to have the Earl of DONOUGHMORE as its treasurer and the same office organisation. Gifts to this second Fund may be earmarked for the purchase of radium through the National Radium Fund. The Keeper of the Privy Purse indeed writes of the two funds as having now been amalgamated. The constitution of the Radium Commission, which is to deal with the custody, distribution, and use of all the radium purchased and held by the Trustees of the Radium Fund, has now been more clearly defined. It is to consist of a chairman appointed by the Trustees and not necessarily a medical man; four representatives nominated, one each by the Minister of Health, the Secretary of State for Scotland, the Medical Research Council, and the Department of Scientific and Industrial Research; and six members to be appointed by the Trustees from a panel to be nominated by the occupants for the time being of the offices of, among others, President of the Royal College of Physicians of London, President of the Royal College of Surgeons of England, President of the Royal Society of Medicine, and President of the British Medical Association. The constitution of the Radium Commission thus provides for an effective majority of members representing the skilled and experienced workers on the staffs of the voluntary hospitals. The Commission, it is stated, is also to have the right of nominating two of the Radium Trustees.

The need for this elaborate care is a measure of the new problem in medicine set by the intrinsic value of radium element. Most of the cost of medical treatment in the past has been the price of the physician's skill and not of the material which he employed; not the paints but the brains with which the paints were mixed, in the words of OPIE'S famous reply as to how he got his wonderful effects. Of course, at one time rare herbs commanded a high price in therapy. A generation or two back a hospital physician might be prescribing for a single pneumonic patient a grain of musk at the equivalent of a week's drug bill for the whole ward; but substitutes for these costly products have been found without disadvantage to the patient. Salvarsan is costly, but its cost is hardly deterrent; the modern organic remedies such as insulin, although a tax on the resources when a long course is necessary, tend to cheapen as a result of mass manufacture; and the possibility of chemical synthesis always looms in sight. Serums and vaccines are not out of the reach of the panel patient who has over and over again been shown not to be at any disadvantage from the low average cost of the drugs and appliances supplied. But in the case of radium, values have completely changed and the stuff is far more costly than the specialist; so serious is the risk of its loss that radium element cannot be removed from the centres where it is used. It is, in fact, far and away the costliest marketable commodity. In times of civil strife and currency depreciation jewellers have been known to carry about their whole capital consisting of a few gems in a vest pocket, but the price of radium is above rubies. The total amount of the element ever extracted may not exceed 20 ounces, at a present money value of £6,000,000, and could (though should not) be carried in the coat pocket. There is a Radium Bank in Paris, and it would be open to a new nation to base its currency on a radium standard with the whole of its reserve in a small lead-lined safe. If, as seems probable, radium is to become one of the essential commodities of medicine, a difficulty to be faced is the fact that the cost of its production is quite unknown, for so far it has only been produced as a by-product by commercial companies engaged in some other form of mining. Until 1923 the carnotite deposits of Colorado were the chief source of supply, but the production there almost ceased after the discovery and exploitation of uranium ore found in the copper mines of Haut Katanga in the Belgian Congo. Since then the annual output of 30 to 40 grammes of radium element has been derived almost entirely from this source. Radium-containing minerals are widely scattered over the world, but the element cannot as yet be extracted from them at a commercial profit. Our own Cornish mines contain low-grade ores for which the Radium Committee does not see any great future. The manganiferous iron industry in South Australia and the felspar works in Ontario offer better possibilities, while promising deposits of pitchblende have been found in the Transvaal, in British India, and in the Tanganyika Territory. No radio-active minerals are at present known to occur in Northern Rhodesia, but that may well be because the geological survey has not been sufficiently pushed to discover them, for Rhodesia adjoins the frontier of the Belgian Congo in which pitchblende ore occurs containing over 50 per cent. of uranium oxide.

It may be wondered, and indeed the question has been asked by thoughtful persons, why such importance should be attached to the emanation from radium element when the most scrupulous care is taken to screen off its peculiar rays which consist of atomic particles or electrons, leaving only the gamma radiation which so closely resembles well-screened hard X rays, that little if any difference has been detected between the action of the one and the other. Why pay millions for extracting a few grammes of radium from tons of foreign ore when their effect can be closely simulated by electric means when the high-tension apparatus has been brought to the necessary pitch of perfection? The reply is a simple one, and fortunately quite conclusive; otherwise no one would feel happy to invest capital in the acquisition of radium element at its present price. The shorter the wave the greater the penetrating power. The gamma rays from radium have about a quarter the wave-length of the hardest rays yet produced, and the apparatus designed to produce these is not only very costly but undergoes rapid deterioration in use. To bring this artificial radiation up to the potency of the gamma radiation from radium would require apparatus which, if it were not beyond the wit of the electro-technician to make, would in the course of a few years cost at least as much in upkeep and replacement as the corresponding amount of radium element. For, incredible as it may appear to anyone except the hardened physicist, radium element can be employed for years without sensible loss. In 20 years the deterioration is only 0·7 per cent.; radium is, in fact, an engine running continuously without working costs.

◆

THE PROBLEM OF MENTAL DEFECT.

THE report of the Special Committee of the Board of Education and the Board of Control is a document that will repay careful study. Wide variations in the estimate of the number of defectives in the country made it essential for trustworthy investigation to precede the discussion of the main problem before the Committee—namely, the best method of educating the educable and training the remainder. Dr. E. O. LEWIS and his assistants carried out a careful survey of six selected areas, and there is no reason to doubt that their findings are applicable to the country as a whole. His report forms Part IV. of the volume just published,[1] while Part I. discusses the origin and scope of the Committee's work, mental defect and legislation concerning it, and Part II. the mentally defective child. Part III., dealing with the defective adult, is not yet available to the public. The conference of the Central Association for Mental Welfare, held last week, and briefly reported elsewhere in our columns, devoted two sessions to the published part, and expressed a strong feeling that the remainder ought to be published immediately in order that the problem may be dealt with as a whole. The most startling feature of the report is Dr. LEWIS's estimate of the number of defectives in England and Wales. He spent two and a half years collecting data in the chosen areas and a year in analysing his results. The magnitude and delicacy of his task are better imagined than described, and the account of it occupies 163 pages. The mean figure for the six areas was 8·57 mentally defective persons per 1000 population; about half of these would be adults. His standards were those agreed upon by the Committee after very careful consideration. They were uniform throughout the investigation and corresponded very closely with those of the Royal Commission of 1906; they are, however, more clearly set out in this report than in any previous investigation. The gross figure for the country is 340,000 persons, of all grades and ages, mentally defective within the meaning of the Mental Deficiency Acts. This is an enormous number, nearly twice as great as that given by the Royal Commission and some 280,000 more than the number of ascertained cases given in the last Board of Control Report. Improved ascertainment does not wholly account for this excess, and the inevitable conclusion is that the amount of mental defect in the country has increased quite definitely during the last two decades.

An important feature of the investigation is the recognition that mental defect must have a social rather than an educational criterion; it is not the inability to attain certain educational standards that constitutes defect, but the inability to use what has been learned in such a way that the individual adapts to the environment in which he finds himself. As Dr. T. BEATON emphasised at the conference, the problem is primarily one of behaviour, and so long as the individual behaves in a manner which does not draw attention to him he is not properly to be classed as defective, whatever his accomplishments in the three R's. A second point of vital importance is the reiteration by the Committee of the fact that there are no sharp cleavages in Nature. A leading educationist declared at the conference that more harm had been done to the progress of mental welfare by the idea that there was a difference in kind, rather than in degree only, than by any other factor. The recommendations for children contain a survey of the very large group of "dull and backward" and put into their proper place at the tail-end of these the certifiably defective. All these children, except those whose mental state is so low that immediate care and control is essential, are to be grouped under the local education authorities for the type of education adapted to their individual degrees of retardation. As a corollary to this, the Committee recommends that the certificate of mental defect, which is at present an essential preliminary to any education other than the routine of the elementary school, shall be abolished. The "special" school would then become part of the ordinary elementary school, and would consist merely of certain special classes with appropriate modifications of curriculum and organisation and a greater degree of individual teaching. The Hadow Report—which should be read along with this one—recommended a break in the general trend of education at the age of 11, and the Committee thinks it would be advantageous if at this age there were a general mental survey of all children with subsequent drafting to the necessary classes, the more retarded being provided with more handicraft training and less theoretical work. The suggested organisation is set out in detail, and it is interesting to compare the Committee's proposals with the experiment described to the conference by Mr. C. J. R. TIPPER. The Westmorland experiment shows what a high degree of success can be obtained in scattered rural areas by willing teachers and wise organisation. In large towns it is not difficult to transfer from schools to occupation centres the gravely retarded children who are detrimental to their fellows and largely ineducable; these are to be notified to the mental deficiency authority and removed from the education authority's purview.

The Committee realises that much remains to be done, for their investigation has inevitably drawn their attention to all those other children for whom the routine education fails to do its best—the shy, the emotional, and the physically handicapped. The report ends with a series of questions and a plea for further research. What has been done, however, is emphatically along the right lines. A great advance is being made towards better housing and better conditions of life and health, but side by side with slum clearance it is possible to watch slums being created afresh under conditions where they need not be. Dr. LEWIS's work suggests that there is a definite relation between the slum problem and the mental defect problem, and that mental deficiency, much physical inefficiency, chronic pauperism, and recidivism are all "parts of a single focal problem." If this be so it is essential that an energetic attack on the problem of mental defect should go hand in hand with other measures for social betterment.

THE ZOO.

THE centenary of the Zoological Society of London was celebrated this week in a fine manner. The scientific value of a zoological collection properly collated and cared for was brought out; the source of instruction and amusement that such a collection is was testified to; and the almost religious feeling evoked by the attempt to preserve species which, unless artificially protected, must perish in the evolution of civilisation found wide expression. All these aspects of the part played in our lives by the Zoological Society were brought out by representative speakers at the two gatherings organised by the Society to mark the celebration. On the afternoon of Monday a formal meeting was held in the great Hall of Universtiy College, London, presided over by the Duke of Bedford, the President of the Society, when delegates from France, Germany, Holland, the United States of America, Scotland, and Ireland were present, as well as many international figures in the zoological world. Here the audience listened first to a witty sketch of the history of the Society given by the President. The foundation of the Society was definitely attributed by the Duke of Bedford to the joint efforts of Sir Stamford Raffles and Sir Humphry Davy, but as early as 1824, three years before the Society obtained its charter, a body of subscribers, of whom the Duke's great-grandfather was one, had obtained an appropriation of ground in Regent's Park, thus becoming the nucleus of the movement later to develop. The Royal patronage, which was definitely accented at a private dinner given by the Society on the evening of the same day by the presence of the Prince of Wales, was manifest from the first in the constitution of the Society, for the personal interest of King William IV. was obtained by the original founders. And this patronage was itself a continuation of a royal tradition, for Henry. I made a collection of wild animals received as gifts from foreign kings, while Henry III. founded a royal menagerie at the Tower of London which existed, though in modified form, at any rate until the days of John Hunter, for that prince of comparative anatomy obtained the right to make post-mortem examinations of animals who died while under the care of the Tower authorities.

The story of the Zoological Society told by the President was followed by an address from Dr. Chalmers Mitchell, the Secretary of the Society, who dealt with the work done in Regent's Park, in words which brought out clearly the developments that had recently taken place both in scientific endeavour and material amenities. We thus learned that not only does the Society celebrate its centenary by recording the possession of the largest number of Fellows in its history, as well as the largest number of visitors to the gardens, but, said Dr. Mitchell, the congratulations received by letter and by delegation from learned bodies all over the world prove that the Society has definitely taken its place in the scientific world by affording the means to foster a vast body of original research. And it is an exact commentary upon this statement to find that practically all the great zoological writers of the last century have made appearance as contributors to the Scientific Transactions published by the Society. It is as a focus for the study of comparative anatomy that the activities of the Zoological Society appeal primarily to the medical profession, and few realise how wide as well as how minute, how exact as well as how suggestive, is the knowledge which has been acquired by medicine from the investigations of the zoologist. In mediæval days, when the dissection of the lower animals was substituted necessarily for that of the human body, the functions of the human organs were often sadly misunderstood from the attempts to draw analogies, with the illogical result that it was the study of comparative anatomy which suffered through prejudice. The credit of elevating that study to its proper position may be attributed to the grant by Charles II. of a charter to the Royal Society, and in great measure to the individual work of Samuel Collins, physician in ordinary to the King. The part later played in the story of medicine by the development of comparative researches, especially in France and England, can be traced in all the literature dealing with the morphology of the human subject and of the lower animals, and regarded only as a laboratory for such inquiries the hundred years of work in the Zoological Gardens must command our gratitude and admiration.

But there is a nobler and wider appeal made by the Zoo than that founded on its services to science. When detailed scientific study can be brought into direct relation with the general emotions, such emotions are quickened and enlarged in range through the possession of an accurate foundation; and those who may be called the unscientific look at the world of natural history with vastly greater pleasure after great object lessons. But this pleasure is shared by the workers in zoology and all who can follow the relations of their activities to medicine. The exponents of exact zoology themselves obtain an intense pleasure from their labours through the knowledge that their investigation of facts is affording an outlook upon nature that could have been obtained in no other way. At the private dinner in Regent's Park the much-travelled Prince of Wales testified to the fascination to be derived from seeing in their native state a large number of the denizens of the Zoo—he pleaded for the use of this convenient abbreviation; and the Belgian Ambassador followed suit in eloquent as well as amusing vein. They were expressing the feelings of countless visitors to Regent's Park, who derive from this grand collection a survey of the wonders of creation, learn much of the doctrines of evolution, and appreciate to the full the intelligent kindness with which the inmates are treated. That the Zoo may continue to prosper is the wish of all, and that it can do other than prosper is unthinkable.

British Hospitals' Association.—The usual separate conferences of the British Hospitals' Association and the Incorporated Association of Hospital Officers were last week replaced by a joint conference held at the University of London, South Kensington, under the presidency of Sir Arthur Stanley. Mr. J. H. Whitley, late Speaker of the House of Commons, opened a discussion upon the Relations between Voluntary Hospitals and Municipal Hospitals under the Local Government Act, and suggested that the conference should nominate representatives of the voluntary hospitals in the various areas who would work side by side with the county and county borough councils. Mr. H. L. Eason uttered a warning against the danger of coöpting upon the new committees persons who have had local government experience to the exclusion of those who hav had experience in the administrative or professional work of the voluntary hospitals. At the annual dinner Mr. Whitley pointed out the advantages that must result from the existence of a hospital council which would enable even the smallest cottage hospital to feel that it was part of a very great and important work. It was stated that hospitals containing 24,000 beds, 11,000 of them outside London, are now subscribers to the federated superannuation scheme.

Annotations.

"Ne quid nimis."

LIFE-TABLES.

IN the fifth annual report of the Registrar-General, published 83 years ago, there is a remarkable panegyric on life-tables. The report is, indeed, *signed* "George Graham," but a belief that—"By these comparisons (i.e., of National Life-Tables) a noble national emulation might be excited: and rival nations would read of sickness diminished, deformity banished, life saved—of victories over death and the grave—with as much enthusiasm as of victories over each other's armies in the field;" argues a robuster faith in the saving virtues of vital statistics than anybody but William Farr has ever possessed. Farr, indeed, was the pioneer in using the life-table as a biometer, holding it to be as "indispensable in sanitary inquiries as the barometer or thermometer and other instruments in physical research." No doubt there was exaggeration in this, but the experience of three generations has proved that, for some important purposes, the life-table is a statistical instrument of medical value. A practical difficulty was that, to the ordinary medical man, the methods of construction, even those of Farr, who knew how little algebra most medical men knew, were more than a trifle perplexing. To Sir Arthur Newsholme belongs the credit of having pointed out to medical men that the (to them) most perplexing stage of the process of construction could be carried out without any resort to algebra. Newsholme and Stevenson proved that a graphical method was quite satisfactory, but there is reason to suppose that students still believe that graduation by formula is, in some mysterious way, more scientific than graduation by the graphic method. On that account we are glad to publish a further illustration, from the pen of Miss H. M. Woods, of the London School of Hygiene and Tropical Medicine, of the simplicity and success of the process. It is true that the use of this method does not dispense the worker from some hours of arithmetical calculation; but the virtue of it is that a medical man, after a very little practice, can confidently perform all the operations intelligently and easily without having to carry in his head, or in a notebook, formulæ the derivation of which he does not understand. There are enough inherent difficulties in statistical work for it to be very desirable that unessential obstacles should be removed. We hope that by recalling the attention of readers to Sir Arthur Newsholme's work, Miss Woods may induce others besides professed students of public health to use Farr's beloved instrument.

DANGEROUS DRUGS ACTS REQUIREMENTS.

THE Home Office has issued a third edition of its memorandum on the duties of doctors and dentists in respect of the Dangerous Drugs Acts and the Regulations made thereunder. It is probably common knowledge by this time that any duly qualified medical practitioner and any registered dentist is authorised "so far as is necessary for the practice of his profession" to be in possession of dangerous drugs and to supply them to his patients by personal administration or by administration under his direct personal supervision and in his presence. The doctor —but not the dentist—may also dispense dangerous drugs for his patient's use and may be in possession of the raw materials for use in the compounding of medicines though he may not supply the raw materials to a patient. Probably the two most important aspects of the law are those which concern prescriptions and the keeping of records. There are some 17 specified drugs which, though they come within the Dangerous Drugs Acts, are specially exempted by the regulations and are purchaseable in Great Britain in the same way as ordinary "poisons" under the Pharmacy Acts. Apart from these specified drugs (which are listed in the Third Schedule of the Consolidated Regulations issued last December) any other dangerous drug (if prescribed in sufficient strength to bring it within the Dangerous Drugs Acts) involves the following duties on the part of the prescriber. The prescribing doctor or dentist must write his prescription, date it, sign it with his usual signature and—except in the case of health insurance prescriptions issued on the official form—must add his address; he must also give the patient's name and address and must specify the total amount of morphine, cocaine, or other drug to be supplied. The only exception to this last requirement is that, where a preparation is prescribed which is contained in the British Pharmacopœia, the British Pharmaceutical Codex, or the Minister of Health's health insurance drug tariff, only the total amount of that preparation need be specified. The Home Office, perhaps not unreasonably, explains that chemists are not allowed to dispense a prescription which does not comply with the foregoing requirements, and the memorandum hints that irregularities do occur, and that doctors must not take offence if chemists ask them to correct an irregularity. A chemist cannot dispense a prescription containing a dangerous drug unless (*a*) he knows the prescriber's signature and has no doubt of the genuineness of the prescription, or (*b*) he has taken reasonably sufficient steps to satisfy himself that the prescription is genuine. As the Home Office points out, this situation can be uncomfortable for the chemist, who may find himself obliged either to delay the prescription (with the prospect of offending the prescribing practitioner) or to break the law. As to the requirement of record-keeping, the memorandum draws attention to the obligation upon a medical practitioner to keep a record of all supplies of dangerous drugs to patients except only in cases where the drug is administered by the practitioner himself or under his direct supervision and in his presence. The memorandum also reprints in an appendix paragraphs 50 to 60 of the report of the Departmental Committee (presided over by Sir Humphry Rolleston) on Morphine and Heroin Addiction. The passages are those which deal with the precautions necessary in administering these two drugs on the one hand in treating addicts and on the other hand in ordinary medical practice; but, indeed, the whole of the Departmental Committee's report (published in 1926 by H.M. Stationery Office at the price of 1s.) is worth study.

The special occasion of re-issuing the Home Office memorandum is the embodiment therein of certain changes in the law due to the operation of the Geneva Convention of 1925—changes which the Dangerous Drugs Act of 1925 was designed to implement. One result is an alteration of the list of drugs within the Dangerous Drugs Acts. The Geneva Convention amplifies the International Opium Convention signed at The Hague in 1912. Among other provisions it creates machinery (through the agency of the League of Nations) for varying the list of narcotics in Chapter III. of the Convention, a list which corresponds with that of the drugs to which Part III. of our Dangerous Drugs Act of 1920 applies. The new machinery will enable the exclusion of any narcotic which is found not to give rise to the drug habit. Part III. of our 1920 Act named morphine, cocaine, ecgonine, diamorphine (or heroin) and their respective salts, and also medicinal opium. Our 1925 Act has a fresh definition of ecgonine and medicinal opium; it explains that cocaine includes synthetic cocaine; and it adds to the list of narcotics in Part III. "any extract or tincture of Indian hemp." Subsequent regulations, however, show that medicinal preparations containing extract or tincture of Indian hemp as one of their ingredients do not come within the Dangerous Drugs Regulations. It remains to add that an Order in Council last August applied Part III. of our 1920 Act to benzoyl-morphine, dihydro-oxycodeinone, dihydrocodeinone, and their respective salts. Subsequent regulations issued last

November enact that no one may have any dealings of any kind in benzoyl-morphine and its salts or preparations without the Home Secretary's licence; the general authorisation which doctors and dentists enjoy in respect of the other dangerous drugs does not apply here. Unquestionably the law as to the use and supply of dangerous drugs is complicated and increases the cares of the busy practitioner. At the same time it must be admitted that the Home Office reasonably met the interests of the medical profession in the matter of the Reference Tribunal and the machinery for withdrawing a practitioner's authority under the Acts; and the recent re-issue of the memorandum is to be commended as an aid to the comprehension of the profession's responsibilities.

EPIDEMIC ENCEPHALITIS AND WAR SERVICE.

IN this country from time to time considerable difficulty has been experienced in deciding how far an ex-Service man's disability, when it takes the form of chronic disease, can be held attributable to his war service. The administrator adjudicating on the question of war pension is naturally guided largely, if not entirely, by medical advice. The medical expert has to consider on the one side that a too ready alacrity to accept all post-war manifestations as due to war service is not only scientifically incorrect, but is making unfair demands on public funds, even although the individual case may excite justifiable compassion; on the other hand, he must remember that too rigid definitions of war diseases may be unjust to the victims of the chronic maladies which had their ætiology during the period of the war and were fostered by military conditions.

That difficulties of this nature have equally arisen in Germany is shown by a paper[1] in which Romberg and Bremer deal with the problem of epidemic encephalitis as a disease attributable to war. At the outset they found that the possible association of epidemic encephalitis and influenza demanded consideration, and were led to the same conclusion as F. Stern—namely, that the time-relations of the two diseases indicate an epidemiological association. In 1918, they point out, influenza was almost universally epidemic on the German front, whole battalions having to be invalided home, and epidemic influenza was both preceded and followed by epidemic encephalitis. They have formed the opinion that true influenza contracted on military service has been followed by epidemic encephalitis, although such a contention is admittedly difficult to prove and no valid statistical evidence is procurable in its favour. They urge that the connexion if not direct may be indirect and the influenza virus which is unknown may activate or endow with pathogenic properties the equally unknown virus of epidemic encephalitis. In 1925, at the request of the German National Welfare Board, Romberg gave a ruling on the war attributability of cases of epidemic encephalitis. Premising that the question is a complex one, he stated:—

> (1) The connexion of epidemic encephalitis with war service must be assumed in all cases where epidemic encephalitis occurred in the field and even in cases where this event is only a probability.
>
> (2) The same connexion must be assumed if an attack of influenza occurred in the field and after the war was immediately followed by the so-called pre-neurasthenic state which merged into the clinical picture of chronic encephalitis.
>
> (3) A similar connexion is assumed if epidemic encephalitis did not immediately follow on the attack of "influenza" in the field, but developed after a certain interval of time during which the individual had been apparently free from disease.

Romberg considers this interval of time should not exceed six months. His third ruling has been the subject of most criticism, but in defence it is argued that it is only applicable to a few special cases. The possible influence of war-strain and war conditions on the ætiology of epidemic encephalitis is not discussed in Romberg and Bremer's paper. It must be observed that the evidence they adduce for the association of influenza and epidemic encephalitis is not very substantial, as they themselves acknowledge, whilst their experience of the occurrence of true "encephalitic" cases in the influenza epidemics of 1890–91 is at variance with the British experience. Again, in the outbreak of epidemic encephalitis in this country in April to June, 1918, when the first wave of the influenza epidemic had appeared, the cases were almost, if not entirely, sporadic and no connexion with cases of influenza was established. A. S. MacNalty considers that the prodromal stage of epidemic encephalitis is often mistaken for influenza, whilst A. J. Hall has pointed out in his Lumleian lectures that if there is any connexion between epidemic encephalitis and influenza it is unusually well concealed from the clinician. The occurrence of an encephalitis due to influenza, although rare, must not be forgotten.

It is probable that by using the term "influenza" Romberg and Bremer have made the attributability of epidemic encephalitis to war conditions more extensive than many neurologists would allow. The difficulties of the position have to be recognised, and it must be agreed that if any error has been made it has been on the side of generosity to the ex-Service man.

THE MACKENZIE MACKINNON RESEARCH FUND.

THE late Sir George Sutherland Mackenzie directed in his will that £30,000 should be paid to the Royal College of Physicians of London and the Royal College of Surgeons of England to form a fund for the promotion of scientific medical investigation. The immediate object of the bequest was to assist students of high intellectual promise by rendering them independent of ordinary professional income whilst carrying out research. The fund he desired "to be named after and in grateful remembrance of my best friend, the late Sir William Mackinnon, Baronet of Balinakill and Loup, to whose unvarying kindness and influence upon me in my youth is due the means and inclination that prompts me to provide this endowment." It was further his hope that others might from time to time add to the fund "feeling like myself that should the conditions be fulfilled the steady coöperation of trained workers may ensure the settlement of questions admitting of doubt and thus prepare the way for the great discoverer who may be destined to throw the light of genius upon problems which their predecessors failed to solve." The annual income from the bequest is at present £1278 and a joint committee of the two Colleges has recommended that it shall be used for the foundation of Mackenzie Mackinnon Fellowships, of which not more than two will be granted annually. Candidates must be nominated for election by a medical school; they will be eligible for re-election, but their tenure of Fellowships will not extend for more than three years except by special resolution of the Colleges.

SPINAL ANALGESIA IN OBSTETRICS.

SPINAL injection is but little employed in this country for the facilitation of labour. It would probably not be incorrect to say that its use in obstetrics is restricted to cases of Cæsarean section where there is definite reason to prefer spinal to any general anæsthetic. Dr. Max Cheval, of Brussels, who has had a wide experience of spinal injection both in gynæcology and in obstetrics, considers[1] that for the latter branch of work it is only exceptionally the method of choice. He does not find that spinal injection facilitates the dilatation of the cervix although he does consider that it abolishes uterine contraction. The indications for the use of spinal injection in obstetrics he holds to be conditions of the patient which forbid general anæsthetics, for example, pulmonary tuberculosis and heart disease, and tetanically contracted uterus threatening rupture. The author gives details of a case refuting the contention of Delmas that with spinal injection dilatation of the cervix is always an easy matter. Other writers [2] on the same ground are more enthusiastic supporters of Delmas, maintaining that the cervix is always well relaxed under spinal analgesia if it is normal to start with. A failure in dilatation of the cervix is due in their view to fibrosis or other pathological change prior to the labour. They also lay stress on the complete relaxation of all the external genital canal and perineum as an additional advantage gained by the spinal injection. On the other hand, they describe difficulty in the method advocated due to hypertonus of the uterine muscle which may render version well-nigh impossible.

SEROTHERAPY IN INTESTINAL OBSTRUCTION AND IN APPENDICITIS.

ONE of the few legacies of the late war which are likely to prove of permanent benefit to humanity has been the elucidation of many problems in anaerobic bacteriology. The work of Weinberg in France has been of great value, and in this country Muriel Robertson and W. E. Gye have made contributions of importance. The fact that *Bacillus welchii*, one of the causal organisms of gas-gangrene, is a normal inhabitant of the intestinal tract leads logically to a search for possible pathogenic effects in its normal habitat. Pernicious anæmia has been related to it with some plausibility, whilst its relation to septic conditions has been investigated in this country by B. W. Williams and in France by Weinberg and his colleagues. A recent publication [3] by the latter summarises his elaborate work on the nature of the infection in acute appendicitis. His technique deserves attentive notice; he has slit open the affected organ, removed fæces, and then made cultures of the inflamed mucosa. In this way he has hoped to get rid of all save the pathogenic organisms, but analysis of the findings suggests that in this respect he is unduly optimistic. Of 160 cases there are no fewer than 23 in which four different organisms, and 16 in which five organisms, are inculpated. Such a multiple infection is certainly not impossible, but it is highly improbable if we may draw deduction from acute infections elsewhere; moreover, the commonest organism is *B. coli*, the normal saprophyte of the fæces. Of anaerobic forms 14 different types of organisms have been found, and apparently their presence is taken as proof of pathogenicity; it often seems to come as a surprise to bacteriologists that the fæces are seldom sterile. Having determined to his satisfaction the nature of the infection Weinberg has proceeded to serotherapy. His view of the multiplicity of the infection has led to the use of a polyvalent antitoxic serum. In particular he includes an anti-*coli* serum, and his work (which is entirely novel) on the production of both toxin and antitoxin to *B. coli* will be awaited with interest. He also includes among other sera the antitoxins of anaerobic forms. The use of these and analogous sera is perhaps more widespread than he realises. He specifically states that no work has been done in this country on the subject, whereas in fact the papers of Williams [4] have attracted a great deal of attention. But Williams's conception is fundamentally different. He argues that in acute obstruction and in the stasis incident on acute appendicitis, there is a proliferation of *B. welchii* in the small intestine, and absorption of toxin without infection. Therefore he treats such cases with anti-*welchii* serum and claims excellent results, largely substantiated by others.

The nature of the toxæmia of obstruction and stasis has long been a mystery. It seems reasonable to suppose that infection is due to one cause and toxæmia to another. The vastly larger number of *B. welchii* in the small intestine (and in almost pure culture) than in the appendix certainly supports Williams's view. Perhaps too much stress may be laid on these distinctions; perhaps, if the view of Weinberg is too extensive, that of Williams is too narrow. At least serum therapy in appendicitis is firmly established, and further work on both sides of the channel may soon determine the best proportion between available sera.

A SET-BACK IN MID-LIFE MORTALITY.

UNDER this heading the Metropolitan Life Insurance Company surveys in a recent bulletin [1] the course of mortality since the issue of the last official American life-table for 1919–20. The previous table (1910) compared with that for 1901 had shown an actual increase in mortality at the higher ages of life, but the misgivings engendered by this finding were to some extent allayed by the experience of the succeeding decade when improvement at nearly every age was in evidence. The outstanding features of the experience of the current decade in the United States of America are a decline in mortality at ages under 37 years and a definite tendency for adult mortality to increase. Most instructive in this connexion is the comparison of the extreme years of the series—1927 and 1921. The expectation of life at birth (mean after-life time) for these two years was 59·10 and 58·01 respectively, a gain of just over one year. At the end of the first year of life, however, the expectations were almost equal—namely, 61·48 and 61·49 respectively. The improvement within the period 1921–27 has thus been secured chiefly by the decline in mortality of infants; higher ages show an actual loss. Similar facts emerge when instantaneous death-rates are subject to comparison. From age 37 till the end of the life-span, mortality in 1927 exceeded that of 1921. The promise given by the experience of the previous decade has therefore not been fulfilled. Possibly in 1921 conditions, so far as concerned adult mortality, were unduly favourable, and the result of such a comparison in consequence too pessimistic. Subsequent to the pandemic of influenza, which played havoc particularly with persons in impaired health, a great decline in mortality at older ages took place, and the deterioration observed at these ages between 1921 and 1927 may simply represent a return from abnormally favourable to normal conditions. Such an explanation, even if true, does not make the figures much less discouraging. The state of affairs is not very dissimilar in this country where the improved expectation of life at birth is in the main due to a declining infant mortality. Some diminution of the deaths at adult ages is surely within the scope of preventive medicine, and there is no reason to believe that mid-life mortality has been reduced to its lowest possible level.

THE UTILISATION OF MILK RESIDUES.

THE Scottish National Milk and Health Association and the Empire Marketing Board have done a useful piece of work by carrying out an investigation of the utilisation of surplus milk and milk residues in Scotland. The investigator appointed was Mr. Archibald MacHeilage, jun., and the result is to hand in the informative Bulletin I. of the Hannah Dairy Research Institute. Prof. E. P. Cathcart, the Interim President of the Institute, in a preface lays emphasis on the fact that the full utilisation of the milk produced is a matter of national importance and that all milk residues, whether skimmed milk, buttermilk, or whey, have a high biological value. The report shows that milk residues produced on the farms are utilised locally by feeding to stock and by sale to bakers and the local population. That this method of disposal is not altogether satisfactory is indicated by the experience of the south-western counties which turn out most of the cheese. There are enough pigs to absorb all the whey but a considerable proportion of the whey is not employed economically.

[3] Ann. de l'Inst. Pasteur, 1928, xlii., 1167.

[4] Brit. Jour. Surg., 1926, xiv., 295; THE LANCET, 1927, i., 907.

[1] Statistical Bulletin, 1929, vol. x., No. 2.

In round figures 114 million gallons of milk are sold off the farms annually, of which 82 are retailed and 32 go to factories or depôts. Of the 32 millions which pass through the depôts, 18½ are retailed, while 7 millions and more than 6, respectively, are used for making cream and cheese. Of the residual separated milk and whey from these two latter processes, it is estimated that 1¾ million gallons of separated milk and 4¼ million gallons of whey are run to waste. It is further pointed out that the amount of skimmed milk run to waste is approximately equal to the amount of condensed separated milk imported into Scotland. In the U.S.A. and Canada the farmers in the cheese-making districts remove their proportion of whey from the depôts and it is reckoned to be worth 1¼*d.* per gallon as a stockfeed. In Scotland this method is not favoured, owing to the risk of the contamination of milk cans and the deterioration of tinware, but some of the depôts have their own piggeries. In Ontario the cheese factories recover the fat from the whey and in Canada in 1925 the production of whey butter amounted to 1,402,573 lb.

The most striking thing in the report is the evidence of neglect of separated milk as a human food. The factories which supply cream do so at a price to cover the cost and profit on the milk from which it is produced so that any return they get by the sale of the separated milk is "found money." The dealers, on the other hand, say the public does not understand the value of separated milk and for their part do not push its sale for fear of bringing about a drop in their sales of whole milk. The average price paid by the Scottish bakers for separated milk is 5*d.* a gallon carriage paid.

SOCIETY FOR RELIEF OF WIDOWS AND ORPHANS OF MEDICAL MEN.

THE annual general meeting of this Society will be held on May 8th, when the Report for 1928 will be presented. The directorate of the Society has suffered severe losses during the year. Its President, Dr. F. de Havilland Hall, died during his term of office, as well as three Vice-Presidents—Sir William Church, Dr. Blackhall Morrison, and Dr. Walter Rigden—each of whom took the keenest interest in its work. The Society at present consists of one honorary, 163 life, and 137 ordinary members—a total membership of 301. The smallness of the membership has been a matter of concern to the Directors and during the year a letter was sent to the deans of medical schools, asking them to draw the attention of newly qualified men to the advantages of joining. The advantages offered are substantial, for the Society is both provident and benevolent. Should a member die and leave his widow with an income not above £125 per annum, she would, on the present scale, receive from the Society a yearly grant of between £75 and £90, and any children under the age of 16 would receive a yearly grant of £60 each. Over the age of 16 special grants may be made to orphans to enable them to continue their education or start in some profession. These grants in many cases amount to £52 10*s.* a year to each orphan. Medical men whose dependents would never be in need of assistance from the funds would be helping the widows and orphans of their less fortunate brethren by becoming annual subscribers or by giving a yearly donation. The amount of the annual subscription is small compared with the benefits that may be derived by unprovided dependents of a deceased member. The annual subscription for a member who at the time of his election is under forty years of age is two guineas; if over forty but under fifty, three guineas; and if over fifty, four guineas. There are special terms for life membership. Membership is open to any registered medical practitioner who at the time of his election is resident within a twenty-mile radius of Charing Cross. Relief is granted to the necessitous widows and orphans of deceased members of three years' standing, and of life members. The invested funds now amount to £140,500, which produced last year an income of £4174 16*s.* Two widows died during the year. One, whose husband had paid in subscriptions £26 5*s.*, received in grants from the Society £2040, the other, whose husband had paid £31 10*s.*, received in grants £990. *The first widow was in receipt of grants for* over thirty years. The sum of £4772 10*s.* was distributed in grants among 50 widows and seven orphans. Application forms for membership may be obtained from the Secretary of the Society, at 11, Chandos-street, London, W.1.

STERILISATION OF THE UNFIT.

DISCUSSION on certain kinds of reform is apt to degenerate into periodic expression of opinion Every now and then promoters and opposers argue hotly, and the unconvinced majority wonder vaguely which of the two groups is right, but in the absence of proof the public interest dies away again for the time being. This to-and-fro method may play an important part in undermining prejudice and insinuating the thin edge of an innovation, but it is unsatisfactory to people who sincerely want to learn what they can about the subject. Lord Riddell's plea for the sterilisation of the unfit, based mainly on the ground of public economy, lacked nothing in eloquence and persuasiveness, but most of the discussion at the Medico-Legal Society last Thursday (reported on page 921) could have been paralleled from previous discussions, and the observer was *left with little more than the conviction that* many authorities believe that sterilisation would be a good thing, while others—backed by the Board of Control and the Central Association for Mental Welfare—believe that it would be either undesirable or impracticable or both. Had John Hunter been among the audience he might well have burst in with his impetuous "Don't think; *try.*" To "try" sterilisation is no simple matter, but since the last general discussion on it was held the results of a big experiment have been carefully assessed by special investigators, and their work merits the considered judgment of all who are concerned to form an unbiased opinion on the results of sterilisation.

There is no commoner and at the same time no more ill-informed argument against sterilisation than the statement: "Oh, it's been tried in America and given up as a failure." The fact is that 22 States have passed sterilisation laws since 1907, and in only one of them has it been repealed. In a few *it has hardly been enforced at all, but in many it is* being put into operation more and more. California stands out because the law has always been applied there energetically, so that during the last 20 years 6255 eugenic sterilising operations have been performed. This number is large enough to form valuable material for investigation, and an impartial inquiry into every possible aspect of the work has recently been financed by a Pasadena philanthropist, Mr. E. S. Gosney. We have already noticed one paper of the series: that in which Dr. R. L. Dickinson concluded that the operative risk involved was almost negligible.[1] As Lord Riddell pointed out, the total death roll in California has been three, while even in the apparently risky salpingectomy, wound infection only occurred in 2·2 per cent. An objection often stressed, and raised by Lord Atkin in a letter to the Medico-Legal Society, is the difficulty of selection and of deciding who shall select. For propaganda purposes it is essential that the promoters of sterilisation should clear their ground on this matter. A great deal of confusion has been caused in the States by the proposal that sterilisation should be used in a penal as well as in a eugenic sense.

---

[1] See THE LANCET, March 2nd, p. 456.

It cannot be too strongly emphasised that—for the present at any rate—the proposal is simply and solely to sterilise the quite hopeless but fertile and well-behaved cases of mental defect. No physician of experience has the slightest difficulty in giving a prognosis for a feeble-minded youth or girl, and few doctors who have to do with these young people would quail before the responsibility of advising sterilisation for a large number. In California no inmate of the State home for the feeble-minded is allowed out unless sterile. Another objection is that the sterilised defective would be a source of immorality and venereal disease. The answer given is that sterilisation makes little difference one way or another to the habits of a defective. If selection is careful and supervision reasonably adequate, no defective of immoral habits will be returned to the community. That this is a feasible policy is shown by a careful follow-up of 605 patients from the California State home. Only one boy—an exhibitionist—showed any sexual delinquency and only 3·8 per cent. of the total were found incompatible, for other reasons, with free social life and the public welfare. Social workers and other trained observers are unanimous in denying any signs in this group of viciousness or tendency to spread disease. These tendencies are still further decreased by the possibility of marriage which—the tragedy of the fertile defective—is to be welcomed for the sterilised as it stabilises their life and increases their happiness. Inquiry showed that of 136 marriages among Californian sterilised defectives two-thirds were successful in that the couple were monogamous, law-abiding, self-supporting, and reasonably happy. Questionaires showed that social workers, parents and relatives, physicians, eugenists and patients were all alike satisfied with the experiment.[2] This fact in itself answers a good many of the honest fears of opponents of sterilisation, and these published results fall into a very different category from speculations of what might happen and unsupported rumours of what does happen "over in America." A cogent objection which the Californian experiment does not counter is that sterilisation can produce so little effect on the number of defectives born that it is not worth doing. It may reasonably be argued, even so, that if it increases the happiness of living defectives and decreases their expense to the nation it is still worth while. On the other hand, Mr. R. A. Fisher has claimed that it might well reduce the incidence of mental defect by 36 per cent. in one generation[3] and though the validity of such figures can only be judged by statisticians, the plain man cannot forget that the children of defectives ought never to be born. Sometimes cruel by nature, more often cruel from ignorance, generally without self-control, the feeble-minded parent is utterly unfit to nurse and train children of tender years. As Mrs. Pinsent has said, "The condition of the children of mental defectives is enough to make the most cynical ashamed of our civilisation." A recent investigation into the clientèle of birth control clinics[4] has shown that these do not touch the problem; the defective mother has not the foresight and sense of responsibility required to attempt prevention on her own initiative.

About the condition of the defective's home and the magnitude of the problem there are no two opinions. We have drawn attention again and again to the terrible disparity between the institutional accommodation available and the numbers needing it. At the latest estimate there are nearly 300,000 irremediable defectives at large, many of them propagating rapidly. Segregation must be slow and enormously expensive. The argument of the steriliser is: Since these people are not on the whole antisocial but their reproduction is a personal and national tragedy, let us submit them to a simple, safe operation which will do nothing to them save prevent conception. The liberty of the individual is infringed daily to protect the community from infectious disease, but mental defect is a graver thing than small-pox or yellow fever, for it threatens the future of the race. The Californian experiment has shown that sterilisation can be carried out on a large scale without any of the evil results feared by the cautious. To object to a measure because it does not solve the whole problem is surely the weakest of all arguments for doing nothing at all. Nobody claims that sterilisation will abolish the need for colonies, institutions, and supervision, but it will give freedom to those who are worthy of it, will reduce public expenditure, and will take its place as an essential element in a complete and well-organised programme of mental hygiene. These arguments deserve a more general and a more thoughtful consideration than they usually receive.

BRITISH CONGRESS OF OBSTETRICS AND GYNÆCOLOGY.

THE Seventh British Congress of Obstetrics and Gynæcology opened in Dublin on April 24th under the presidency of Dr. Gibbon FitzGibbon. The first day was devoted to a discussion on The Management of Cases of Pelvic Disproportion, when Prof. Munro Kerr opened with a paper on The Diagnosis of Pelvic Disproportion, by (*a*) instrumental, (*b*) manual, (*c*) radiographic methods. He pointed out that there is by all methods great difficulty in arriving at exact measurements of the pelvic inlet, but that deformities of the outlet could be exactly determined. The selection of treatment for deformity of the pelvis at the inlet therefore depended on an exact estimation of the relative size of the head to the pelvis; but for the outlet treatment should be based on exact measurement of the outlet. He emphasised the importance of recognising minor deformities, as failure to do so resulted so often in unsuitable treatment being employed. He believed that the largest proportion of disasters occurred in this group. In conclusion, he pointed out that the practical question was—will the head pass? He referred to the factors which influenced spontaneous delivery: (*a*) previous obstetric history; (*b*) any irregularity in pelvic brim; (*c*) size of fœtal head; (*d*) degree of ossification; (*e*) variety of biparietal obliquity; (*f*) strength of uterine contractions. A report of the proceedings will follow in our next issue.

Members of the Congress were entertained at luncheon at the Royal Hibernian Hotel on the opening day by the local council, and, in the evening the President and Mrs. FitzGibbon held a reception in the Royal College of Surgeons, which was largely attended. The Congress Dinner was held on April 25th at the College with the President in the Chair.

Sir George Blacker has been appointed President of the Radium Institute in succession to Sir Anthony Bowlby (deceased), and Sir Hugh Rigby's name has been added to the Committee of the Institute.

THE 161st exhibition of the Royal Academy of Arts is on the eve of being open to the public. Two of the outstanding portraits in the exhibition are of distinct medical interest, namely, that of Lord Moynihan by Mr. Richard Jack, and that of the Rt. Hon. Neville Chamberlain, the Minister of Health, by Sir William Orpen. Both are admirable presentations.

THE amount of the Central Practitioners' Fund for the year 1928 has been finally determined at £6,191,750, of which the London Insurance Committee's share is £882,079. The amount due to this Committee in final settlement is £30,752. The total payment for the year works out at 8*s*. 11·725*d*. per unit of credit; the corresponding figure for the year 1927 was 8*s*. 10·447*d*. This represents an average capitation fee in 1928 of 9*s*. 0·031*d*., as compared with 8*s*. 10·87*d*. in 1927.

THE NATIONAL RADIUM FUND.

THE following letter appeared in the *Times* of April 20th :—

Sir,—It is now established that in the treatment of cancer radium is an essential instrument; month by month this becomes more manifest.

The medical profession in its attack upon cancer is seriously hampered by the grievous insufficiency of the supply of radium in this country. And it is well to remember that this disease is not confined to those who are worn by age or debility, but attacks vigorous men and women in the full plenitude of their usefulness.

This fact is illustrated by the statement that 4000 women, many of them mothers of families, die yearly in England and Wales from cancer of the womb.

The need for radium is great and urgent, and the supply is altogether inadequate to meet the need. There thus exists a grave situation. Human life is at stake—and with it the nation's reputation.

In these circumstances we ask to be allowed to appeal through your columns to the whole nation for the money wherewith to purchase radium on a scale adequate for this pressing purpose.

Radium is, however, very costly and a large sum of money will be needed. To secure an adequate supply for present and forthcoming needs there will be required £250,000.

His Majesty's Government has promised to make a grant of £1 for every £1 subscribed up to a limit of £100,000, so that our appeal to the generosity of the country is for £150,000.

The radium will be bought and held by a body of Trustees which has the confidence alike of His Majesty's Government and the medical profession. It will be administered by a Commission which will contain an effective majority of members representing the skilled and experienced workers on the staffs of the voluntary hospitals.

We suggest that contributions to the National Radium Fund will commemorate in a way peculiarly impressive the thankfulness felt for the King's convalescence after so dangerous an illness. This national appeal and that being made by King Edward's Hospital Fund for London are acting in close coöperation and have the advantage of the same treasurer and office organisation.

Contributions should be marked "Radium," and sent to Treasurer, Thank-Offering Fund, 103, Kingsway, London, W.C.2.

JOHN ROSE BRADFORD,
President, Royal College of Physicians; Member of General Council, King Edward's Hospital Fund.

MOYNIHAN,
President, Royal College of Surgeons.

FLORENCE E. BARRETT,
Consulting Gynæcological Surgeon, Royal Free Hospital.

E. FARQUHAR BUZZARD,
Regius Professor of Medicine, Oxford.

DAWSON of PENN,
President, Royal Society of Medicine.

ROBERT A. FLEMING,
President, Royal College of Physicians, Edinburgh.

GORELL,
Chairman, King's College Hospital.

THOMAS HORDER,
Member, Advisory Committee, British Empire Cancer Campaign.

KNUTSFORD,
Chairman of the London Hospital.

J. P. LOCKHART-MUMMERY,
Chairman, Executive British Empire Cancer Campaign.

EWEN J. MACLEAN,
President, British Medical Association; Senior Gynæcologist, Cardiff Infirmary.

J. M. H. MACLEOD,
President of the Section of Dermatology, Royal Society of Medicine.

ALEXANDER MILES,
President, Royal College of Surgeons, Edinburgh.

READING,
Chairman, British Empire Cancer Campaign.

HUMPHRY ROLLESTON,
Regius Professor of Medicine, Cambridge; Chairman of Imperial Cancer Research Fund.

ARTHUR STANLEY,
Treasurer, St. Thomas's Hospital: Chairman of the British Red Cross Society.

STANMORE,
Treasurer of St. Bartholomew's Hospital.

STCLAIR THOMSON,
Emeritus Professor of Laryngology, King's College Hospital.

JOHN BLAND-SUTTON,
Vice-Chairman, British Empire Cancer Campaign.

The Clinical Interpretation of Aids to Diagnosis.

A Series of Special Articles contributed by Invitation.

XXIX.—THE INTERPRETATION OF BASAL METABOLISM TESTS.

A CLEAR understanding of the value of basal metabolism tests in clinical medicine must be based on a knowledge of the physiology and technique of the test, and of the factors which may cause deviation from the normal in health and disease.

The rate of heat production in the body varies throughout the day and night according to the amount of physical and mental activity. In order to compare the rate of heat production of different persons measurement must take place under certain arbitrary conditions, and the state found to be most convenient for comparison is when metabolism is reduced to the minimum necessary to keep the body alive under conditions of complete rest. Metabolism reduced to its lowest level is known as basal metabolism, and for practical purposes is most nearly attained after a night's rest in the horizontal position, no food having been taken for 12 hours and no movement having taken place before or during the test. For the rate of heat production in different persons to be compared allowance must also be made for differences in weight and height, or what is found to be more exact, for differences in surface area. In practice the latter is calculated from the two former factors, and the unit of comparison is taken to be the number of calories produced per square metre of skin per hour under basal conditions. Lastly, allowance also has to be made for the normal variation for age and sex. When all these factors have been taken into account, the basal metabolism is expressed as a percentage above or below normal for the size, age, and sex of the subject. Variations of 15 per cent., plus or minus, may occur in patients who are otherwise apparently normal.

Technique.

The *Douglas bag* method is the one most commonly used in this country for estimating the basal metabolism. Briefly, the method is as follows. A sample of expired air is first collected under basal conditions over a measured period of time. The amount of CO_2 in the sample, the total amount of expired air, and the respiratory quotient are then measured, and the amount of oxygen absorbed calculated from these data.

An alternative method which in careful hands is sufficiently accurate for clinical purposes makes use of the *Benedict student apparatus.* The subject breathes into a closed circuit containing oxygen, a measured quantity of pure oxygen being introduced as it is absorbed. The time taken for the absorption of a known quantity of oxygen is measured, and from this data the basal metabolism is calculated. This method is quicker than the Douglas bag method, but is less accurate.

Whatever method is used, it is important that its accuracy shall be confirmed from time to time on a series of normal controls.

For accurate estimations it is important that the subject shall breathe normally both before and during the test, since nervousness and excitement, by increasing the muscular effort of respiration and causing over-breathing may lead to a large error. This applies particularly to patients with hyperthyroidism. It is important, therefore, for patients to become accustomed to breathing into the respiration apparatus before the actual measurement is made. Mental excitement during the test must also be avoided. Du Bois describes the case of a patient in a large calorimeter whose metabolism unaccountably rose 10 per cent. It was finally discovered that the patient had seen through the window of the calorimeter someone whom he disliked intensely. The amount of practice required before normal respiration is established varies greatly in different patients. The first estimation, however, should always be discarded, as the error is likely to be high.

Sources of Error.

To appreciate the clinical value of these tests it is necessary to understand the many ways in which error may arise. The greatest regulator of the rate of metabolism is the thyroid gland. It has been shown in a large series of cases of myxœdema that for every mg. of thyroxin absorbed the basal metabolic rate is increased by 2·5 per cent. Consequently it is in diseases of this gland that basal metabolism tests are most often made. There are, however, other states of disease in which the metabolism may be altered, and these must be allowed for in interpreting basal metabolism readings in thyroid disease. To give a crude example, extreme undernutrition and hyperthyroidism may be associated in the same patient. The former will tend to lower the metabolism and the latter to raise it, so that the resultant reading will be far from an indication of the degree of hyperthyroidism. During starvation the basal metabolism falls to a low level. Benedict's experiments on the fasting man, Levanzin, showed that heat production fell gradually from the start, and was 30 per cent. lower on the twenty-first day of starvation. In states of moderate undernutrition there is evidence to show that the metabolism is almost unchanged, while in children between the ages of 8 and 12 there is an increase. The effect of fever on the basal metabolism is profound and must never be forgotten. According to Du Bois, the average increase is 7·2 per cent. for every degree (Fahrenheit) of rise in temperature. In simple or constitutional obesity no very marked deviations from the normal have been proved. In that associated with hypopituitarism there is a lowering in some cases. In diabetes mellitus the depression of the basal metabolism has been shown to be proportional to the severity of the disease. In mild cases it is normal, while adequate insulin treatment tends to restore the metabolism to normal in severe cases. In secondary anæmia the observations of Boothby and Sandiford reveal a normal basal metabolic rate in nearly all cases, whereas in pernicious anæmia their cases showed a raised rate. In leukæmia and polycythæmia the basal metabolism is, according to most authors, definitely high.

From the foregoing list it can be seen how essential it is to assess basal metabolism results in conjunction with clinical findings, and when using the test in thyroid disease the possible effects of coexisting disease of another kind must not be forgotten.

Myxœdema.

Myxœdema is caused by a diminution in the secretion of iodothyrin by the thyroid gland, and the basal metabolism may fall as low as 50 per cent. below normal. In such severe cases a single estimation is useful in confirming the diagnosis and in giving an estimate in figures of the severity of the disease, and an idea of the amount of thyroid which will be required in treatment. The actual dosage, however, must be regulated more by the clinical condition than by the actual test. The state of the cardiovascular system is all important, for severe cases of myxœdema often have myocardial degeneration; thus any speeding up of the metabolism of the body, which throws extra strain on the heart, must be done slowly and cautiously. Clinically the test is of greater value in diagnosis in borderline cases of myxœdema, in cases of other disease in which a coexisting thyroid deficiency is suspected, and in partially treated cases of myxœdema coming under observation after previous indiscriminate treatment. In such cases a reading of 15 per cent. below normal is strongly suggestive of thyroid deficiency. Repeated estimations during treatment with thyroid preparations are of greater value than single estimations in judging the dosage required to maintain the metabolism at a normal level.

Estimations of basal metabolism might be of great value in the early diagnosis of *cretinism.* Unfortunately the difficulties of performing the test accurately in children are very great, and no method has yet been devised which is of practical value in routine clinical work.

Hyperthyroidism.

In conditions of over activity of the thyroid gland basal metabolism tests have their greatest clinical application. In severe cases of both exophthalmic goitre and toxic adenoma single controlled estimations are a useful confirmatory indication of the severity of the disease, while tests repeated at intervals are used to indicate progress during treatment. In very severe cases of hyperthyroidism the rate may rise to 100 per cent. above normal. In moderately severe cases +40 per cent. is a frequent figure. Of the clinical signs the pulse-rate is the sign which bears the most constant relationship to the metabolic rate. This relationship may, however, be disturbed by additional cardiac complications, such as annular fibrillation or myocardial degeneration. Above 40 per cent. the diagnosis is usually clear and does not need instrumental confirmation. In severe cases isolated tests are therefore of little use, and may worry the patient unnecessarily. Repeated tests, however, at intervals of a week or ten days are of great value in estimating the patient's reaction to rest and medical treatment and the urgency of operation. In borderline cases of hyperthyroidism the test is of diagnostic value. The syndrome of nervousness and tachycardia is a common one, and it is often difficult to distinguish the rapid pulse-rate and nervousness of functional disease from early Graves's disease. A basal metabolic rate raised 15 per cent. in such a case strongly favours the latter diagnosis. Here it must be remembered, however, that the nervous patients are just those who may have most difficulty in breathing normally during the test, and are likely to give an error on the high side.

In cases of long-standing goitre the test has the same value in the diagnosis of oncoming hyperthyroidism, for once this is confirmed by a basal metabolism raised 15 per cent. or more operation becomes an imminent consideration.

The foregoing remarks apply to cases of hyperthyroidism in which no iodine has been given. Iodine has a profound and as yet unexplained action on the basal metabolic rate in exophthalmic goitre, and if it has been given this fact must be taken into consideration. When it is first given the basal metabolism in nearly every case falls to a normal level in from one to three weeks while iodine is continued. At the same time the signs of the disease grow less; the exophthalmia, tremor, and nervousness abate, and the pulse is slowed, although it rarely reaches normal. As a result of the diminished metabolism the unpleasant sense of heat experienced disappears and the patients are cooler and quieter. This state of affairs is not maintained, and after a period of a few days or weeks, even if iodine is still given, the basal metabolism rises steadily again and there is a parallel clinical relapse, though this does not reach the former level of severity for some time. If iodine is discontinued the relapse is sudden, and the basal metabolism rises rapidly. In a few cases there may be clinical relapse without a corresponding rise in the metabolic rate. I have seen two patients who had been taking Lugol's iodine continuously for six months, and although they both showed all the signs and symptoms of severe exophthalmic goitre, their basal metabolic rates were −9 and −13.

The clinical interpretation of basal metabolism readings in patients with hyperthyroidism who have been taking iodine must, therefore, depend on a consideration of the history of iodine medication. Isolated estimations in those who have been taking iodine irregularly or for a long period are of no value. The most useful application of iodine in exophthalmic goitre is in producing an artificial remission of the disease at the time of operation and preventing post-operative crises. Ideally the best time for operation would appear to be when the basal metabolism has been reduced to normal or as near normal as possible with iodine. A series of estimations during the period of preparation will determine when this optimum has been reached, and is then a useful confirmation of clinical observation.

The test is also of value when, in spite of a partial thyroidectomy, some signs of hyperthyroidism persist or recur. Then a constant increase of 15 per cent. or more may indicate the necessity for removal of a further portion of the gland. Occasionally cases occur after operation in which a rapid pulse and slight exophthalmos are associated with other signs suggestive of myxœdema. In such mixed cases constant readings either above or below normal give a better indication of the activity of the thyroid gland than clinical observation.

Conclusion.

To sum up, basal metabolism tests are of greatest value to the clinician in borderline cases of hyper- or hypothyroidism. Readings of 15 per cent. above or below normal are strong confirmatory evidence of a disordered output of the thyroid gland. Repeated estimations are useful in following the course of a disease and its reaction to treatment. There are, however, other causes, apart from thyroid disorders, which alter the metabolism, and these must also be considered in interpreting results. As Mackenzie has pointed out in the study of heart disease, the goal of precise methods is to enable us to dispense with them as soon as we have learned all that they may be able to teach us; so it is with basal metabolism tests, but at present they form a useful aid in diagnosis and in checking treatment.

MODERN PHYSICAL TREATMENT IN RELATION TO RHEUMATISM.

BY R. FORTESCUE FOX, M.D., F.R.C.P.,
PRESIDENT OF THE LIGUE INTERNATIONALE CONTRE LE RHEUMATISME.

II.[*]—CONTINENTAL PRACTICE AND TEACHING.

IN the early part of last century a widespread popular movement originated in Central Europe for the use of external remedies, and especially of cold water. The peasant, Priessnitz, established his "water-cure" on the Gräfenburg in 1830 and formulated, with real genius, a regimen of simple habits and diet, with baths and applications, exercises and perspirations, which certainly proved itself of spectacular benefit to large numbers of sufferers from chronic ailments. Unfortunately, in the hands of his followers this teaching became too soon a rigid and lifeless system. Rickli followed, with his "atmospheric cure" on the shores of the Austrian lake Valdes (now Yugoslavia). He upheld the healing virtues of light and water and air; water was from the earth, air was an intermediate agency and, most potent of all, light came from the heavens. Such invocation of the elements, although a revival of ancient teaching, was in sharp opposition to the accepted medical teaching of the times. The traditions of Rickli still linger in the establishments in that country dedicated to "natural remedies." Lastly came Father Kneipp at Wörishofen, near Munich, who preached to throngs of health-seekers from all countries the virtues of cold water in the morning air and sunshine. Elderly patients are still living who tell of the astonishing benefit they derived for a languid circulation and cold extremities from walking barefoot in the dewy grass.

This recourse to physical remedies by multitudes of persons of all classes seems now an almost instinctive movement of reaction from artificial medication. If only we could give to our medical instincts the support of knowledge and to our medical knowledge the authority of instinct! It became necessary to study seriously these unsuspected or neglected methods of treatment. In Central Europe the movement of investigation was led by Winternitz, one of the earliest and greatest pioneers in modern hydrology. His Principles of Hydrotherapy were formulated in 1877, and from that date onwards he amplified and illustrated his theme in a remarkable series of experimental studies carried on in his clinic at Kaltenlautgeben near Vienna. To the work of Winternitz and of his pupils, many of whom are still living, is attributable a great part of the existing knowledge, still far from complete, of the actions and uses of heat and cold upon the human body in health and disease.

In the present century hydrotherapy and other forms of physical treatment have been brought into fresh prominence by their use for military cases in most European countries as well as in America, Canada, Australia, and New Zealand. One idea, or hypothesis, or method, or technique, succeeds to another, and it is not unnatural that the use of some particular form of energy such as radiotherapy, heralded by dazzling discoveries, should temporarily occupy the entire field without regard to its indispensable allies.

Hospital Departments in Germany.[3]

In most general hospitals physical treatment of one kind or another, such as electricity and massage, is employed, and in some of these hospitals, as in England, the physical departments are becoming more comprehensive.

A physical treatment department of a comprehensive character forms a constituent part of the great *Barmbeck Hospital* at Hamburg. Four pavilions are allocated to this section, which is under the direction of Prof. Eric Plate. About 1100 patients, for whom physical methods of treatment are considered desirable, are admitted to the hospital every year. Heat and movement in many forms are employed for rheumatic cases and simple apparatus for measuring the deformity and immobility of joints. Just emphasis is laid upon complete investigation of the patient's general condition, since a disturbance of other functions is often associated with articular disease. Three laboratories are attached to the physical section, and a considerable amount of original work is carried on.

The physical treatment department at the *Rudolf Virchow Hospital* at Berlin, of which Dr. A. Laqueur is the director, has no beds, but serves for in- and out-patients from the entire hospital. The methods of treatment employed are five—water, mechanical treatment, diathermy, light, and electricity. In the last year the number of treatments given was in round figures as follows: water, 34,000; mechanical treatment, 10,000; of the other three, each 8000. The average duration of physical treatment was from four to six weeks. A similar department under the direction of Dr. Ernst Freund forms part of the University Clinic at Vienna.

A physical section at the great civil hospital at *Strasbourg* was opened by the Germans in 1912, mainly for the insured population, and serves for the hospital itself and for out-patients from the city. The large central bathing hall is maintained at a temperature of nearly 70° F. and contains a circular pool divided into sectors at different temperatures.

---

[*] Part I. appeared last week.

[3] Fox and Mautner, M.: Appendix to Ministry of Health Report on Chronic Arthritis, London, 1928.

Around the room there are compartments and appliances for treatment by vapour, fango packs, douches, radiation, &c. Various forms of local treatment, such as diathermy, hot air, and manipulation, are given in a suite of rooms on an upper floor.

Spas and Sanatoria.

In continental countries, as in England, the chief spas are equipped for comprehensive physical treatment. All well-established spas may be regarded as health resorts for physical treatment, in which the local waters and climate play an essential part. But of late years, and especially since the war, when the cult of rays has rather dazzled the world, radiotherapy and the other accessory physical methods of the spas have been multiplied and magnified and in many places have temporarily eclipsed the use of the waters.

A reaction is now in progress. It is recognised that the multitudinous conditions presented by differing forms of incipient and chronic disease require many kinds of physical treatment, and that the value of the spas and health resorts must in the end rest upon their natural endowment and their distinctive methods.

Physical treatment, including in each case the local spa treatment, is used at the spa hospitals even more extensively than in England. The local baths and waters, with accessory methods, were much used for disabled soldiers at the military spa hospitals in France and the Pro Patriá Hospital at Pistany and in many other localities. Recent buildings like the Landesbad at Aachen have been even more completely equipped for combined physical and spa treatment. The extensive use of physical methods, including hydrotherapy, in public and private sanatoria throughout Central Europe must not be forgotten.

Clinics for Physical Treatment in the Towns.

A large proportion of the patients treated at the physical departments of hospitals and at the spas in Germany and Austria are insured persons. The great medical and social significance of the health insurance system may be gauged from the fact that insured persons now number in many places, as in Strasbourg, nearly one-half of the population. In Germany and Austria they are members of friendly societies (*Krankenkassen*), by whom facilities for treatment are arranged. So large, however, are the numbers of the insured, intellectual as well as manual workers, for whom special methods of treatment are required, that it has become necessary to set up clinics for physical and other forms of treatment in the towns. These clinics are in fact in those countries provided by the societies for the benefit of their members.

A palatial new clinic of this character has been lately opened in succession to smaller establishments at Hamburg. In Saxony what are called the "natural methods" of treatment have long enjoyed great popularity, and it is significant that the amount now spent by the societies, in Dresden for example, for baths and massage exceeds one-third of the total payments to chemists and druggists. At the great clinic at Dresden, which was opened just before the war, the figures showing the total number of treatments for the last available year are approximately: water, 90,000; light, 48,000; electricity, 47,000; inhalations, 9000; exercises and mechanical treatment, 8000. From 400 to 500 cases are here treated daily. It is stated that the milder forms of treatment by baths and hot air are especially popular in Dresden with rheumatic patients, who sometimes wish to continue such treatment when it is no longer necessary on medical grounds.

In Berlin the associated societies, with nearly a million and a half members, have more than 40 ambulatoria or out-patient clinics. In these establishments medical advice is given to the members on a great variety of special subjects. Physical treatment of one kind and another is installed at most of these clinics. The Central Ambulatorium in Berlin is equipped with a complete hydrotherapeutic department, with baths in porcelain and wood, for various forms of medical baths, as well as appliances for hot air and vapour, fango, light, diathermy, and mechanical treatment. The current figures show a total of 157,000 treatments per annum, of which about one-half were given in the hydrotherapy department.

Many other town clinics have been set up by the societies in German and Austrian cities. At some of these large numbers of cases are treated. The establishments vary very much in equipment, in their medical and general organisation, and in the degree of skill and accuracy with which the treatment is carried out. Although many of them are doing excellent work, there appears to be at most of these clinics little or no effort made at serious investigation, either of the cases treated or of the methods of treatment employed. Moreover, although they follow identical objects and methods, their organisations appear to lack central guidance and coördination.

Current Teaching.

The current medical teaching on physical treatment in Germany has been recently set forth in some recent handbooks by several of its leading exponents. Dr. Laqueur[4] bases his conclusions on many years' experience in his department in Berlin where some 3000 cases annually are under treatment by physical methods. Like the other authors cited, it is his practice to use hydrotherapy in conjunction with radiation, electricity, and movements. There is general agreement among all these writers that the value of hydrotherapy is insufficiently recognised, both in acute and chronic disease. Laqueur holds that recent work has clearly established the action of baths upon the vegetative nervous system and blood pressure and also their stimulant action upon metabolism in addition to their more local effect in the production of hyperæmia.

Dr. George Hauffe, in his most recent work,[5] reaffirms conclusions which are founded on experimental work carried out at Dr. Kraus's University Clinic at Berlin. Hauffe has studied the effects of cold and heat upon the circulation in the partial or half-bath, given at a slowly increasing temperature, often up to the limits of toleration. Changes in the distribution of the blood are shown by the plethysmograph attached to the *untreated* arm. The arm bath at temperatures rising to 42° C. produces an increase of volume in the arm, but it is interesting to note that experiments on healthy and diseased individuals show different results. Hauffe holds that any kind of slowly increasing stimulus may produce an increasing dilatation of the peripheral vascular system, whilst violent or sudden stimuli of all kinds cause contraction of this system. The "reservoir of the circulation"—that is to say the heart, pulmonary circulation, and the larger vessels of the body cavities—is distended when the peripheral circulation is contracted and vice versa. This statement may be compared with the fact that in the tropics and in hot baths the amount of blood circulating in the skin may be enormously increased (according to some observers up to 50 times the normal), a fact which led Joseph Barcroft to suggest that the volume of circulating blood may be temporarily increased.[6] Hauffe believes that, since the coronary and bronchial vessels belong to the peripheral system, the state of nutrition of the heart and lungs can be deduced from a study of the cutaneous vessels. The physician, he adds, who wishes to understand hydrotherapy must be willing to get his hands wet, just as the surgeon gets used to the knife.

[5] Hauffe, G.: Physikalische Therapie des praktischen Ärztes, Berlin and Vienna, 1926.

[6] Quoted by Sandstroem: The Physiological Aspects of Tropical Climates, Phys. Rev., April, 1927.

A convenient and systematic handbook on hydro- and thermo-therapy[7] is the work of Dr. Ernst Tobias, who has for many years conducted a course of instruction for practitioners. He deals with all the most convenient forms in which heat is applied in practice, especially in the treatment of nervous disease. Whilst the peripheral sensitiveness to pain and touch is increased by short applications of heat or cold, prolonged warmth, as in "sedative" baths, *greatly diminishes this sensitiveness. The hypothesis* of Goldscheider is cited that the stimulation of thermal nerves inhibits the spinal pain centres, and that "the sensation of warmth displaces the sensation of pain."

Dr. Walter Krebs, who is in charge of the large Landesbad Hospital for the Rhine provinces at Aachen, has written a short treatise on the foundations of hydrotherapy.[8] In this hospital all kinds of physical treatment are given, as well as surgical and medical treatment of other kinds, and important research work is being carried on in connexion with the German Society for Combating Rheumatism. It is, in short, an "arthritic unit" of the type foreshadowed by the British Ministry of Health.

(To be concluded.)

A NOTE ON THE

GRAPHIC METHOD OF GRADUATION IN THE CONSTRUCTION OF LIFE-TABLES.

By HILDA M. WOODS,
ASSISTANT LECTURER IN EPIDEMIOLOGY AND VITAL STATISTICS, LONDON SCHOOL OF HYGIENE AND TROPICAL MEDICINE.

ALTHOUGH the importance of expressing mortality data in life-table form can be exaggerated (Greenwood),[1] the use of life-tables in affording summary comparisons of place with place or epoch with epoch is considerable. In the past, medical men have been rather daunted by the "mathematical" appearance of the methods of construction. It has been our experience in the Division of Epidemiology and Vital Statistics of the School of Hygiene and Tropical Medicine that even the short methods, facilitated by Dr. E. C. Snow's tables, do not appeal to the, unfortunately, numerous medical men who look on equations or formulæ with mingled awe and aversion. There is not, of course, any magic about arithmetical methods of graduation. The only superiority they possess over the dexterous use of a lead pencil is that, *if* the necessary sums are worked out accurately, all the users of the same formulæ must reach the same results, while no two wielders of a pencil will draw precisely the same curves. The practical question is whether the answers differ to an extent which matters in any public health application.

The graphical method of interpolation was first employed by Milne in the construction of the Carlisle table in 1815, but for a long time there was much uncertainty as to the precise method he used to obtain the population and deaths at the individual age-periods. It was not until 1883 that King[2] proved conclusively that Milne had adopted graphical interpolation to obtain his values. Graduation by the graphical method is extremely simple and requires little knowledge of mathematics. Briefly the process is as follows: to find the number of lives at risk for individual years of life from the quinquennial and decennial groups of ages, mark off along the abscissa line equal portions for the quinquennial groups of ages and double length for the decennial age-groups; then construct a series of rectangles equal in dimensions to the population at each of the separate age-groups, and draw a continuous curved line through the upper part of each of the rectangles. The curved line must never change its course so as to form an angle in its path, it must so cut each of the rectangles that the area cut off is equal to the area added, and the sum of the values read off from the curved line bounding the space above must be equal to the total area of the rectangle. The same process is followed to obtain the deaths at individual ages from the deaths in age-periods.*

Newsholme used Milne's graphic method in the *construction of the Brighton life-tables (1881–90* and 1891–1900), and the same process was adopted by Tattersall for the Oldham life-table (1881–90). No attempt was made to compare the result of the graphic method with that of mathematical formulæ until Hayward[3] discussed improved analytical methods for the construction of life-tables and tried his formulæ on the Brighton data 1881–90. He found, somewhat to his surprise, that, comparing Newsholme's values for the expectation of life, the graphic method gave a remarkably close approximation to the result of the analytical. He also showed in a later paper[4] that inconsistent results could be obtained by employing different analytical methods, and it was not wise to compare life-tables unless they had been calculated on a uniform plan. Newsholme and Stevenson[5] discussed the comparative value of the two processes for constructing life-tables, and in the same paper published a full and clear description of the graphic method based on the experience of Brighton in 1891–1900. They pointed out that neither the graphic nor the analytical method could be relied upon to give accurate results for ages 0–5, nor for ages 85 and upwards, owing to the untrustworthiness of these ages of the census and death returns. For intermediate ages they considered that the graphic method was undoubtedly preferable to the analytical because it was easier, more expeditious, and the results (see table below reproduced from Newsholme and Stevenson's report) were in close agreement with those obtained by the analytical.

Brighton (Males) Life-table, 1881–90.

"G." = graphic method (Newsholme). "A." = analytical method (Hayward). Diff. "A.," "G." = differences of "A." from "G."

—	"G."	"A."	Diff. "A.," "G."	—	"G."	"A."	Diff. "A.," "G."
E_0	43·59	43·56	—0·03	E_{45}	22·36	22·36	±0·00
E_5	52·87	52·88	+0·01	E_{55}	16·48	16·46	—0·02
E_{10}	49·12	49·12	±0·00	E_{65}	10·96	10·94	—0·02
E_{15}	44·67	44·66	—0·01	E_{75}	6·64	6·58	—0·06
E_{20}	40·55	40·51	—0·04	E_{85}	3·33	3·46	+0·13
E_{25}	36·51	36·51	±0·00	E_{95}	1·68	1·2	—0·46
E_{35}	29·02	29·04	+0·02				

As a further test I applied the graphic method to the data of England and Wales for 1901–10, and compared the expectations of life with those found by King for the same period (English life-table No. 7, males). My results are in such close agreement with those of King that it seemed worth while putting the results on record.

With the England and Wales data one is dealing in millions, not as in Newsholme's case in thousands, and it was not, of course, possible to obtain the same degree of accuracy in reading off the figures from the curve without constructing a curve on such a large scale as to become unwieldy. The central population for the individual years of life were only taken to the nearest 10,000, and the numbers dying at each age in hundreds, but, as will be shown, this did not materially worsen the results. The distribution under five years was based on births and deaths, and from age 85 upwards the curves of populations and deaths were reconstructed on a much larger scale. Newsholme used the method of differences for this part of his table for the sake of greater exactitude. No attempt was made at refinement with the England and Wales figures, the aim being to work out the table on the simplest possible lines.

* For a full description of the method see Newsholme and Stevenson, Jour. of Hyg., 1903, iii., 297.

Expectation of Life. England and Wales, 1901–10.

G.M. = graphic method $\overset{\circ}{e}_x$. K.E. = King's English life-table. No. 7, $\overset{\circ}{e}_x$. P.c. diff. = per cent. difference.

Age.	G.M.	K.E.	P.c. diff.	Age.	G.M.	K.E.	P.c. diff.
0	48·91	48·53	0·8	45	23·35	23·27	0·34
5	55·97	55·90	0·13	50	19·81	19·76	0·25
10	51·92	51·81	0·21	55	16·54	16·48	0·36
15	47·43	47·31	0·25	60	13·56	13·49	0·52
20	43·12	43·01	0·26	65	10·82	10·80	0·19
25	38·98	38·86	0·31	70	8·37	8·39	0·24
30	34·94	34·76	0·52	75	6·48	6·41	0·11
35	30·90	30·79	0·36	80	4·70	4·86	0·33
40	27·07	26·96	0·41	85	3·58	3·53	0·14

Although the results of the graphic method, compared with King's figures, rather over-estimate the expectation of life, the difference never amounts to 1 per cent. Such small discrepancies suggest that results sufficiently accurate for all practical purposes can be obtained by this simple method of graduation.

PARIS.

(FROM OUR OWN CORRESPONDENT.)

A General Medical Council for France.

THE scandals in the medical profession, recently given unsympathetic publicity in the lay press, have brought to a head a scheme which has long been brewing, and which only needed the impetus of several shady transactions to coax it into the open. This scheme is nothing short of a General Medical Council, which, it is hoped, will enable the medical profession to put its own house in order. Its essential features were outlined by Prof. V. Balthazard at a recent meeting of the Académie de Medécine. As he pointed out, the medical corporations in former times, acting under the ægis of the Faculties of Medicine, kept their members very strictly in the narrow path of virtue, and long after the disappearance of these corporations their disciplinary influence survived. The law of 1884 did not equip the medical syndicates with the necessary means to enforce discipline; for not only were doctors free to decline membership thereof, but the syndicates were unable to impose their will in delicate matters of medical etiquette. A syndicate might blame, or, in extreme cases, exclude from its membership a peccant doctor, but such action did not necessarily terrify him into better ways.

The sort of council which Dr. Balthazard asked the Académie de Médecine, as chief guardian of the interests and honour of the medical profession, to recommend to the Government, is a body which would control every doctor, and which would have powers enabling it in extreme cases to deprive an offender of his legal right to practise medicine. Anticipating the objection that the lay tribunals already deal with offences committeed by doctors, Dr. Balthazard remarked that such tribunals are incapable of dealing with the doctor who lapses into charlatanism, who advertises himself in a manner calculated to discredit his profession, or who gets entangled in collusionary transactions which are ethically, rather than legally, shady. After discussing the proposed machinery of this new body, which is, of course, to be composed of doctors elected according to certain well-defined rules, and from the decisions of which appeals can be made to a yet higher power, Dr. Balthazard gave an account of the ethical code by which the new Council would be guided in its decisions. On a later occasion it would be interesting to review this code at some length, and as a foretaste of this review, it may be noted that, in the matter of dichotomy, a business-like solution is proposed. It is suggested that the medical practitioner shall be entitled, with the full cognisance of his patient, to a percentage of the special fees, his share being proportional to the importance of the part he plays himself, and never exceeding 25 per cent. On the recommendation of the President Dr. Balthazard's proposition was referred to a special committee of which he is a member. In discussions of this kind the Anglo-Saxon doctor must sometimes ponder over his Latin confrère's use of the term "client" when speaking of the person described in Anglo-Saxon countries as the "patient." Is it that we Latins are more commercially minded than our colleagues on the other side of the Channel? Or are we simply (one hesitates to suggest a train of thought culminating in any claim to superiority) more candid?

SCOTLAND.

(FROM OUR OWN CORRESPONDENT.)

Cruelty to Children.

THE Royal Scottish Society for the Prevention of Cruelty to Children continues its admirable work under the Children Act. This society is, I should think, unique in Scottish administration in one respect—namely, it has a statutory function under the Children Act. It has power to make investigations into all cases of cruelty that are brought to its notice and to take the initiative in bringing the facts before the responsible authorities. The Children Act is extremely difficult to administer, and the welcome it had as the "Children's Charter" has ended, on the whole, in disappointment. The primary reason no doubt is that there is no single authority responsible for its administration as a whole. Meanwhile, the Cruelty Association, or, as it is known among the people affected, "The Cruelty," continues, in its own field, to maintain its high standard of work as a voluntary body acting officially. Of over 100 cases coming before the society last year less than 4 per cent. ended in prosecution. This means that 96 per cent. of the cases are handled directly by the society officials.

The Campaign against Tubercle.

The Royal Victoria Hospital Tuberculosis Trust continues its activities from year to year. This is the fortieth anniversary of the Victoria Dispensary for Tuberculosis. The idea of the dispensary as the basis of a comprehensive scheme was converted into reality by Sir Robert Philip long ago and has spread over the world. The Victoria Dispensary opened its door in Bank-street, Edinburgh, on Nov. 22nd, 1887. At that date it stood alone. The 40 years have allowed the committee gradually to develop the extensive programme of the Edinburgh scheme. Following the Victoria Dispensary, the scheme included the establishment of the sanatorium (the Royal Victoria Hospital) tuberculosis school, the working colony, the sanatorium colony of Southfield, the tubercle free dairy farm, and the Chair of Tuberculosis in the University. In 1914 the committee transferred in gift to the city of Edinburgh three large institutions which constitute the chief factors in the corporation's tuberculosis equipment.

This year's report, therefore, is important as containing the historical beginnings of a very great movement. Although tuberculosis continues to be a serious cause of crippling and death, its fatal grip is everywhere relaxing. Every local authority in Britain now has a scheme of greater or less comprehensiveness, and the attack of all forms of tuberculosis is maintained with unfailing force. Yet the cases continue to occur in their thousands, and we are very far from mastery anywhere. The disappointments with methods have been numerous, although there has been much good result. But the disappointment has usually been due to the failure to recognise the universality of the infection and the failure to act early enough.

> "One of the most significant advances has been the gradual shifting of the doctor's outlook from the adult or adolescent patient to the child. . . . A remarkable result of the widespread acceptance of this view is to be found in the now frequent requests from doctors, both medical officers to local authorities and private practitioners, for the admission of young children to Southfield. This is all to the good. Still, much more is needed. . . . The advent of tuberculous infection—almost inevitable under present conditions—should be watched for and appropriate measures taken to ensure that the infection becomes practically innocuous. The adoption of this procedure as routine practice by every doctor would hasten immeasurably the ultimate disappearance of gross disease."

Meanwhile, there is abundant room for research, and workers are not without hope that one day a direct antidote will be discovered.

The Hospital Question.

In Scotland it is becoming clearer that with the steadily increasing demands on the part of the public for hospital accommodation for diseases like pneumonia and influenza, coöperation of the voluntary hospitals with the public bodies is essential; but where such coöperation is readily given the position of the voluntary hospitals is being made more and more secure, since the official hospitals, by careful adjustment, can enable the voluntary hospitals to do the best work they are capable of in higher medicine and surgery. It is to be expected, as time goes on, that the hospital treatment of bronchitis, rheumatism, and other general diseases will steadily demand more accommodation. So far as Scotland is concerned, however, the new local government measure promises well.

At the Elsie Inglis Memorial Maternity Hospital 712 patients were admitted in the year ending Nov. 30th. This was a falling off, as against the previous year, of 152, but the decrease was due to the increase in the number of antenatal cases admitted involving a prolonged stay. There were in all 279 weeks of antenatal care as against 186 in the previous year, and this is a good index of the trend of modern treatment. In the three and a half years since the hospital was opened the experience of the patients from the neighbourhood has shown the special need of antenatal rest and care and a higher standard of health for the expectant mother.

IRELAND.

(From our own Correspondent.)

An Outbreak of Enteric Fever.

There has recently been a serious outbreak of enteric fever in the town of Carrick-on-Shannon which has now been traced to a grossly infected water-supply. The water-supply comes from the river Shannon, and the intake is by a pipe which is not more than 15 feet from an open drain carrying the sewage from the fever hospital. Between Jan. 6th and March 14th eight typhoid patients from the neighbourhood of Ballinamore were treated in the fever hospital. Dr. Robert McDonnell, one of the medical inspectors of the Department of Local Government and Public Health, has investigated the outbreak, and his report was published last week. He found that owing to leakages and breaks in the pipe there was direct connexion between the fever hospital sewer and the pipe carrying water to the town. He recommends that a water-supply should be provided from a new source, and he suggests Corbally Lake as a source. As long as the town is dependent on the river for its supply it is always in danger of an epidemic. The village of Leitrim is on the banks of the Shannon, only four miles above Carrick, and a single case of enteric occurring in that village would be a serious menace to the health of the people of Carrick. Dr. McDonnell adds that the conditions in Carrick are the direct result of the complete absence of health organisation. If the county had the services of a county medical officer of health with a trained sanitary staff the outbreak could not have occurred. He adds that many of the medical practitioners in the county neglect their statutory duty of notifying cases of infectious disease. The outbreak has caused several deaths, including that of the member of the Dail for the district.

UNITED STATES OF AMERICA.

(From an Occasional Correspondent.)

Medicinal Use of Alcohol.

In curious contrast to the news reaching us from England that alcohol is now prescribed much less frequently than it was a few years ago are some statistics recently published by the Bureau of Prohibition of the Treasury Department. In those States which permit the use of liquor for medicinal purposes there are 116,756 licensed physicians. Of these 48,097 were prescribing alcohol in 1927, while last year the number had risen to 68,951. Each physician who prescribes must apply for permission to do so, and if this is granted he is allowed four books of prescriptions per annum. During 1927 one book each was used by 14,948 doctors, two books by 8743, three books by 10,861, and the maximum of four books by 13,545—a rather curious distribution of frequencies. The total number of prescriptions issued during the year 1922 was less than 9 million, in 1927 the number was a little under 12 million—a maximum of 13½ million being reached in 1925. The career of prohibition appears to be reaching something of a climax. Everyone is looking to the new President with the expectation that he will find some way to correct the abuses that have grown up under the administration of the 18th amendment. The "Jones" law, which increases the penalties inflicted on bootleggers, seems to have put a good many of these out of business for the time at least. There is a possibility that juries in some States will refuse to convict under this new law. On the other hand, the State of Wisconsin which voted for Hoover in the presidential election has now recorded an enormous majority against the State prohibition law. This is a blow to the "drys" who have interpreted the result of the presidential election as a mandate for prohibition. The success of prohibition is, perhaps, most fundamentally jeopardised by the now widespread habit of manufacturing wines in the home. Attempts to prevent this involve the need for trespassing upon domestic privacy which in turn is bound to cause popular resentment. A recent incident in Aurora, Illinois, where "dry" agents entered a home forcibly (and it seems illegally), knocked down the father of the family and shot his wife dead, has aroused a nation-wide indignation which is highly significant.

Autopsies in Hospitals.

The Council of the American Medical Association adopted a ruling in 1926 that after Jan. 1st, 1928, hospitals, to secure the recognition for the training of internes of the Association, must perform autopsies in at least 10 per cent. of the deaths occurring in their institution. At the beginning of the present year the requirement was to have been advanced to 15 per cent. The decision has greatly increased the number of autopsies performed, the number of hospitals meeting the first requirement having increased from 64·4 per cent. in 1926 to 93 per cent. in 1928. However, it has been decided to postpone the higher requirement for one year to give some deserving institutions a chance to catch up with others that have been more successful. It is pointed out that those who have succeeded have been able in some cases to secure the coöperation of the public by furnishing a report of the autopsy to relatives who are naturally interested in knowing the cause of death. The maintenance of a well-kept autopsy room to which visitors can be shown is also said to be of assistance in this regard.

NOTES FROM INDIA.

(FROM OUR OWN CORRESPONDENT.)

The Teaching of Psychiatry.

IF there is one department of medicine which is conspicuously the Cinderella of Indian medical schools it is that of mental diseases. This is no fault of the mental specialists. Indeed, there are several distinguished psychiatrists who, for many years past, have lost no opportunity of emphasising the urgent need of better teaching facilities for students in their department. The difficulty is, in part, the inadequate provision of hospital accommodation for mental cases on modern lines, which is notoriously expensive; in part the remoteness of existing mental hospitals in comparatively rural surroundings, far from the main teaching centres. But whatever excuse may be made, the lack of facilities is incontestable. Lieut.-Colonel Berkeley-Hill, who feels keenly on the matter, points out, in a lecture recently given at Delhi,[1] that although the term mental hygiene is itself of modern origin, since its introduction in 1907 many advances have been made both in the prevention and cure of mental disease, and that the example of America in founding an association for mental hygiene in 1916 was soon followed by France and England, in both cases with far-reaching results. It may be held, perhaps with justice, that the spate of societies and associations in India does not lead to any increase in honest spade-work, but this is a case where not only the public, but the governments central and provincial, need instruction and stimulation, and there is need for propaganda by some authoritative body. Quite recently the Director of Public Health in the Bombay Presidency, himself a Parsi, drew attention to the prevalence of insanity in the Parsi community, which he attributed to consanguineous marriage. Other Indian communities are addicted to this custom, but no doubt many causes contribute to mental instability, and the first step in the correction of dysgenic racial proclivities is the collection and dissemination of knowledge. This function a society of mental hygiene would be well fitted to carry out.

The Campaign against Leprosy.

A good example of organised inquiry and propaganda is furnished by the progress of the campaign initiated in 1925 by the British Empire Leprosy Relief Association. The situation in India is much more perplexing than it is, for instance, in the Philippine Islands. In Luzon, the large island on which Manila is situated, the population consists principally of Christians, and it was here that the American administration, with characteristic vigour, put into practice many years ago a scheme of wholesale segregation which they were hopeful would exterminate the disease within a generation. A small island was available for isolation, with another nearby for relatives and friends visiting; the people were, on the whole, docile, and easy communication by sea facilitated transit and made it possible for a roving medical commission to carry out inspection. The procedure, it appears, has not been as successful as had been expected, and any such wholesale regulation would have been impossible in India, with its diversities of race and creed. Indeed, even in the Philippines it was considered unwise to go so far with the turbulent Mohammedan population of the island of Mindanao. The tendency in India has been to proceed on the lines of least resistance. The number of lepers, even according to the incomplete census returns, is enormous, and it has been left to private charity and to the exertions of the Mission to Lepers, supplemented by small grants from public funds, to deal with the problem on an infinitesimal scale by the establishment of asylums.

Now, however, in the space of a few years, and with the assistance of very moderate funds (the result of a viceregal appeal which, unfortunately, coincided with a period of financial stringency) the Leprosy Relief Association has put a new spirit into the crusade. Recognising from the start that any kind of extensive scheme of compulsory segregation was out of the question, the Association concentrated on research and propaganda, coupled with facilities for instructing selected members of the medical profession in treatment and policy. In the words of Dr. E. Muir, who is in charge of this department at the Calcutta School of Tropical Medicine and Hygiene, "the old methods of forcible segregation of only that small proportion of the known leper population which exposed itself in begging on the roads—a section, by the way, consisting largely of non-infectious 'burnt-out' cases—are being replaced by voluntary clinics, the training of doctors in the most recent methods of diagnosis and treatment, investigation into local causes of high endemicity, and propaganda based upon such investigation." A party has made sample surveys in Bihar, Bengal, Burmah, the Central Provinces, and Bombay, and where the incidence is heaviest it is hoped to start special leper clinics, or if funds are not at first available for that, to establish leper departments in connexion with existing dispensaries. Some clinics are already in operation, and enough information is now available to show that good results may be hoped for along these lines. As Dr. Muir remarks, although we do not yet possess any single remedy which can be called a specific, we have at our disposal treatment which, when properly administered, will, in the great majority of early cases, rid the patient of all active signs and keep him well, provided he continues to take the proper precautions, and which will also heal up a large proportion of the advanced cases. The effect of recent action is already evident from the way early cases, which formerly hid themselves in despair at the absence of treatment, and through fear of social ostracism, are coming forward to take advantage of the newer methods, where these have been brought to their notice. That the spread of the good news is still very restricted, is, however, well exemplified in a case which came before the Allahabad High Court only four months ago,[2] in which a leper, disgusted with life, was actually helped by his friends and relatives, including his ten-year-old son, to commit suicide by throwing himself into the Ganges. This incident took place near the city of Meerut. A procession was formed, the voluntary victim was bathed, dressed in clean clothes, and fed on sweetmeats, after which he was taken to the river bank and pushed in by his friends and relations.

It is not very long ago since *mata devi*, or small-pox, was everywhere regarded in India as an inevitable scourge of the gods. Surely people who have had the intelligence to appreciate the benefits of vaccination may be expected to display similar discernment in the case of leprosy, and to accept the relief which modern methods of treatment offer.

AUSTRALASIA.

(FROM OUR OWN CORRESPONDENT.)

Treatment of Cancer in New Zealand.

Mr. Sampson Handley's visit to New Zealand has served to focus attention on the facilities for treating cancer in the Dominion. On reviewing the stocks of radium, he gives it as his opinion that the amount available is almost enough to make a serious start with treatment, although the quantities at Auckland and Dunedin seem rather inadequate. There is not enough, however, to make it possible to use all the current methods of employing radium. At present about 320 milligrammes are in use at Auckland, 1 gramme at Wellington, 508 mg. at Christchurch, and 280 mg. at Dunedin. Mr. Handley advocates the establishment of a central institution for the treatment of cancer. He proposes 50 beds for a start, with special cancer wards in other large cities. He further recommends that an experienced histologist be appointed in connexion with the main cancer hospital, and that one of the surgical staff should go abroad for special study. Finally, he urges the necessity of educating the public in the early signs of cancer. His address has received a good deal of notice throughout the daily press of Australasia.

The Health of New Zealand.

New Zealand has always had an enviable record for infant mortality, and figures available for the urban areas (which include over half the population) show that there will be an even lower infant mortality-rate for 1928. There has been a definite downward trend during the past five years, the figures per 1000 births for the urban areas, commencing with 1923, being 50·1, 44·9, 44·7, 44·5, 45·1, and 41·4 in 1928. The last figure thus shows a decided fall. It is expected, moreover, that the final rate for 1928 for the whole population of the Dominion will be even lower, as the Dominion rates compared with the rates for urban areas have been invariably lower for deaths and infant mortality and higher for births. The Dominion rate for 1928 will be awaited with interest; for 1927 it was 38·7. The urban birth-rate, on the other hand, has been the lowest on record, 17·7 births per 1000 of the population. The death-rate shows an increase of 0·07 per 1000. There were no epidemics during the past year, but scarlet fever, diphtheria, and influenza took a greater toll of life than in the previous year. Other diseases showing notable increases were tuberculosis, cancer, heart disease, and pneumonia. Deaths from motor and railway accidents increased, but those from measles, diseases of the nervous system, bronchitis, senility, and diseases of early infancy decreased.

Venereal Disease.

The prevention and control of venereal diseases in Australia is undertaken by the State. Each State has a Venereal Diseases Act, or provisions in the Health Act governing the measures taken to combat these diseases, and in each State anonymous or impersonal notification has been made compulsory. Unfortunately, it is realised that by no means every case is notified by the medical practitioners. What relation exists between notification and incidence can only be guessed at, but probably two-thirds of the cases are notified. The crude incidence-rate for Australia (notifications only) for 1927 was 243 per 100,000 of the population. The figures per 100,000 for the respective States are: New South Wales, 239; Victoria, 304; Queensland, 147; Western Australia, 243; and Tasmania, 170. The figures for South Australia and the territories are not available. The review of the notifications for the past five years shows that there has been a slight fall for the Australian rate from 297 in 1922 to 243 in 1927.

Noise and Health.

Stimulated by the regulations prescribed in France, whereby the sounding of motor-car warning signals is prohibited between the hours of 1 A.M. and 5 A.M., the medical officer of health for Brisbane has suggested to the city council that an ordinance be drafted for the suppression of unnecessary noise. The point was made that the excessive use of the motor horn at intersections is usually an expression of laziness on the part of the driver, and it is safer and less noisy to slow down at intersections than to blare a way through a crossing on the principle of the "survival of the noisiest." Further suggestions have been made to create zones of silence in the residential areas of the city and to exercise a more strict control over the noise made by shunting operations in the railway yards, especially the auditory insult occasioned by letting off steam.

Mental Deficiency in New Zealand.

As part of the administrative machinery of the Mental Defectives Act, 1928, a board has been appointed to control the care, treatment, and training of the mentally deficient in New Zealand. One of the board's first duties will be the compilation of a register of all persons who are "socially defective." Any person whose name is so entered will have the right of appeal to a Supreme Court judge. The board also has the power to establish clinics for the diagnosis and treatment of mental cases. These clinics will be conducted by qualified psychiatrists. Considerable modification of the sterilisation proposals were made during the passage of the Bill.

MEDICINE AND THE LAW.

A Boy's Death from Mercury Poisoning.

AT an inquest held at Islington on April 23rd the death of a boy was attributed to syncope resulting from acute colitis brought about by mercury poisoning. The boy's mother had previously stated that the boy had been under treatment at St. Bartholomew's Hospital for a skin rash. On March 22nd she was given a box of grey powders at the hospital; she gave the boy the box to carry, and, before she could stop him, he swallowed two of the powders in the street. When she got home she placed the box on the mantelpiece; after the boy's death (two days later) she could not find the box and powders. Sir Bernard Spilsbury said the prescription for the powders contained mercury; he did not think two powders would have a serious effect on the boy, but if the boy took more it might have had a fatal result. After an adjournment of the inquest for the purpose of chemical analysis of the internal organs, Dr. G. R. Lynch gave evidence of finding traces of mercury. There was one-twelfth of a grain in the kidneys and he thought mercury poisoning was the cause of death. Two similar deaths from mercury poisoning were on record. A verdict of accidental death was returned. The coroner, Sir Walter Schröder, said very definite instructions were given with the powders at the hospital but, in view of the evidence, he came to the conclusion that the boy had swallowed an excessive number.

Overdose of Ether.

A child nine weeks old died while under an anæsthetic at King's College Hospital. The evidence at the inquest at Camberwell on April 23rd was that the anæsthetic was administered by the assistant casualty officer of the hospital who said that he had been qualified for about a week, and had administered altogether about 120 anæsthetics, about 25 by himself. The child was undergoing a minor operation; 25 minutes after the operation had begun breathing stopped; oxygen was given, artificial respiration was at once tried, and restoratives were injected, but without success. The second casualty officer, who had been qualified for four months, said he was supervising the operation (which he had himself performed almost daily for the last three months), while a dresser conducted it. There was no undue hæmorrhage; the senior casualty officer was called when the case went wrong. Questions were asked by Mr. Douglas Cowburn, the Camberwell coroner, indicating his opinion that the operation took too long, and that a more experienced anæsthetist would have noticed earlier that something was amiss. He explained to the child's mother that death was due to an overdose of ether, though he added that the doctors concerned (who greatly regretted what had occurred) had done everything possible in the endeavour to save its life afterwards. Mr. Cowburn did not, it appears, condemn the practice of permitting dressers to perform simple operations in a teaching hospital, but he described the degree of supervision as unsatisfactory in the sense that the doctors present had so recently been qualified. A verdict of accidental death was recorded.

Public Health Services.

INSTRUCTION IN SMALL-POX.

THE Metropolitan Asylums Board have arranged a course of instruction in the diagnosis and treatment of small-pox, to be held at Joyce Green Hospital, Dartford, Kent. The first demonstration was on May 1st, and the dates and times of the subsequent demonstrations will be notified by the clinical instructor to students attending the class. Further courses will be held from time to time as may be necessary and practicable. The fee for the course, which will consist of three demonstrations, is £1 1*s.*, provided that students who may be receiving, or who may have received during the past six months, instruction in fevers at the Board's hospitals will be permitted to attend without payment of a fee. Students will be conveyed between Dartford Station and Joyce Green Hospital free of charge. Those who desire to attend must satisfy the Board that they are sufficiently protected against small-pox by vaccination or otherwise. Qualified practitioners may attend the demonstrations without any fee. Application to the Clerk to the Board, Victoria Embankment, London, E.C.4.

INFECTIOUS DISEASE IN ENGLAND AND WALES DURING THE WEEK ENDED APRIL 29TH, 1929.

Notifications.—The following cases of infectious disease were notified during the week:—Small-pox, 374 (last week 339); scarlet fever, 1902; diphtheria, 1067; enteric fever, 39; pneumonia, 1287 (last week 1743); puerperal fever, 44; puerperal pyrexia, 93; cerebro-spinal fever, 22; acute poliomyelitis, 4; acute polio-encephalitis, 3; encephalitis lethargica, 15; dysentery, 8; ophthalmia neonatorum, 121. No case of cholera, plague, or typhus fever was notified during the week.

The cases of small-pox were notified from the following 26 counties:—London, 49 (viz., Bethnal Green, 4; Camberwell, 7; Holborn, 7; Islington, 1; Lewisham, 1; Poplar, 2; Shoreditch, 1; Southwark, 1; Stepney, 25); Chester, 2 (Ellesmere Port); Cornwall, 1 (Stratton and Bude); Derby, 36; Dorset, 1 (Sherborne); Durham, 32; Isle of Ely, 1 (Whittlesey); Essex, 69 (of these West Ham, 66); Gloucester, 1 (Dursley); Huntingdon, 3 (Norman Cross); Kent, 2 (Gillingham, Gravesend); Lancaster, 16; Leicester, 3 (County Borough); Middlesex, 4 (Tottenham, 1; Willesden, 3); Northampton, 26 (County Borough); Northumberland, 2 (Tynemouth); Soke of Peterborough, 4 (Borough); Somerset, 1 (Clutton); Southampton, 1 (Farnborough); Stafford, 31 (of these Stoke-on-Trent, 30); Warwick, 2 (Birmingham, Coventry); Wilts, 7 (Swindon); Yorks, West Riding, 46; Flint, 1 (Prestatyn); Glamorgan, 27; Monmouth, 6.

The number of cases in the Infectious Hospitals of the Metropolitan Asylums Board on April 23rd–24th was as follows:—Small-pox, 276 under treatment, 13 under observation (last week 200 and 10 respectively); scarlet fever, 1479; diphtheria, 1752; enteric fever, 14; measles, 119; whooping-cough, 1154; puerperal fever, 21 (plus 7 babies); encephalitis lethargica, 79; poliomyelitis, 4; "other diseases," 54. At St. Margaret's Hospital there were 10 babies with ophthalmia neonatorum.

Deaths.—In the aggregate of great towns including London there were 2 deaths from small-pox, 2 (2) from enteric fever, 58 (1) from measles, 5 (1) from scarlet fever, 96 (37) from whooping-cough, 39 (11) from diphtheria, 65 (18) from diarrhœa and enteritis under two years, and 161 (32) from influenza. The figures in parentheses are those for London itself.

The deaths provisionally classified to small-pox were assigned to Manchester (C.B.) and Gillingham (M.B.). No great town reported more than 10 deaths from influenza. Liverpool reported 11 deaths from measles, Newcastle-on-Tyne 6, West Bromwich and Birmingham 5 each. The widely distributed deaths from whooping-cough did not exceed 4 in any large town, except Manchester with 5. The highest figures for diarrhœa are Salford and Blackburn with 4 each.

The number of stillbirths reported during the week was 288 (corresponding to a rate of 38 per thousand births) including 53 in London.

Deaths from Small-pox.—Two cases of small-pox, one from the district of Sale and one from Manchester City, which died in the Manchester Small-pox Hospital, were passengers on s.s. *Tuscania.* Dr. W. StC. McClure, acting medical officer of health for Manchester, tells us that Case 1 was a male, aged 44 years, who landed at Liverpool on April 1st and began to be ill on the 3rd; the eruption appeared on the 5th. He was removed to hospital on the 6th and died on the 10th of confluent hæmorrhagic small-pox. He was vaccinated for the first time on March 31st. Case 2 was a male, aged 34 years, who landed at Liverpool on the 1st, began to be ill on the 4th; the eruption appeared on the 6th. He was removed to hospital on the 7th and died on the 14th of confluent hæmorrhagic small-pox. He was vaccinated in infancy, one mark ¾ square inch, and was revaccinated successfully on March 31st.

The Services.

ROYAL NAVAL MEDICAL SERVICE.

Surg. Rear Admiral E. Sutton is placed on the Retd. List at own request.

Surg. Lt.-Comdrs. J. Wylie and H. L. Douglas to be Surg.-Comdrs.

The following appointments have been notified:—Surg. Lt.-Comdrs. (D.): C. Williams to *Greenwich;* R. R. Adams to *Ganges;* D. Paterson to *Pembroke;* and W. E. A. Sampson and M. F. Hopson to *President*, for three months' post-graduate course.

Surg.-Lts. (Short service): T. W. Froggatt, G. Phillips, and C. B. Nicholson transferred to Permanent List.

ROYAL ARMY MEDICAL CORPS.

MILITIA.

Maj. L. A. B. Moore retires on attaining the age limit.

TERRITORIAL ARMY.

Col. C. R. White to be Hon. Col. R.A.M.C. units, 53rd (Welsh) Div.

Maj. W. T. Briscoe resigns his commn. and retains his rank, with permission to wear the prescribed uniform.

Maj. A. F. Hewat resigns his commn.

Capt. G. Sparrow (late R.A.F.) to be Capt.

Lt. E. A. Wilson to be Capt.

2nd Lt. C. R. L'E. Orme, from Gen. List (T.A.) to be Lt.

R. Anderson to be Lt.

TERRITORIAL ARMY RESERVE OF OFFICERS.

Maj. (Bt. Lt.-Col.) C. H. Lindsay resigns his commn. and is granted the rank of Col., with permission to wear the prescribed uniform.

Lt. D. L. Greig from the Active List to be Lt.

INDIAN MEDICAL SERVICE.

Capt. Sankarankoil Chidambaranatha Alagappan to be Maj.

Lt.-Col. W. M. Anderson retires.

Maj.-Gen. W. H. S. Nickerson, late R.A.M.C., has been selected for appointment as Director of Medical Services in India in succession to Maj.-Gen. Sir Walter H. Ogilvie, I.M.S., who will retire in September.

Correspondence.

"Audi alteram partem."

THE EFFECTIVE USE OF RADIUM.

To the Editor of THE LANCET.

SIR,—In your leading article of April 27th you state that "in this country there is no centre where the method (the use of large quantities of radium at a distance from the body) is being used." It would be a pity if the files of THE LANCET carried down to history a wrong impression of the progress of radium work in this country in the year 1929. It is in use at Westminster Hospital. It is impossible to work for long with needles, radon seeds, cavitaries and surface appliances and remain satisfied. It is not enough to deal with localised primary growths and glandular metastases. The greater the encouragement gained from dealing with these, the stronger the compulsion to attempt control of extending primary growths and visceral metastases. No X radiation is yet available with frequency of high gamma-ray order. One must, therefore, test gamma-radiation ("teletherapy") as soon as a quantity of radium is available that makes it at all possible.

At Westminster last December a gramme of radium became available. An apparatus was designed for us (by F. R. Carling) suitable for the space at our disposal, and adequate for us to gain experience. A 24-hour service was necessitated almost from the first. Already it has been of great use to us. It is much too early to speak of results—good or bad; but we have learned (1) the desirable features to be embodied in the design of our more permanent apparatus; (2) something of the effects upon the blood, metabolism, general well-being and morale of advanced cases; (3) that our fears for the skin were exaggerated; (4) that we must modify our ideas of the mode of action of radium. We were aware, of course, for physical and mathematical reasons, that it would be desirable to have two or two and a half grammes in the apparatus. We hope to be entrusted with such a quantity, but we do not now think that the four grammes employed on the Continent is really necessary. Although we badly want more needles and more radon, we are satisfied that concentration of half our available radium in one apparatus has been amply justified.

No doubt you will agree that premature publication of results would be an error, but we welcome visits from all who are really interested in the subject, and in fact, a good many visitors from radium centres have already so honoured us.

I am, Sir, yours faithfully,
E. ROCK CARLING.

Westminster Hospital, S.W., April 26th, 1929.

To the Editor of THE LANCET.

SIR,—I have read with interest your leading article with this heading last week, but I cannot help doubting whether your arguments are sound. It seems to be your belief, in agreement with Dr. G. E. Birkett's letter, that the ideal to be aimed at in radium treatment is likely to be found in the so-called "bomb," giving a beam-irradiation from a distance. This may be true, and the method must assuredly be exploited, but it is clear that for many years to come its application on a large scale will be quite impracticable, for even a State-organised radium supply will not be adequate. It is our duty, therefore, to progress as far as natural limitations permit with the development of the "surgery of access" and the implantation of needles or seeds.

You state, however, that it is *obviously* impossible to obtain uniformity of irradiation of a tumour by any such method. To me this is not obvious at all. In fact, with so accessible a tumour as a carcinoma of the breast it is, in practice, [illegible] easy. Furthermore, a uniform irradiation can also be given to a larger area of lymphatic drainage than can be dealt with by operative surgery. You are pleased to regard my attitude as "courageous" (an epithet which so often carries a hidden implication of "foolhardy"), but I wish to suggest that the method practised at St. Bartholomew's and at several other hospitals is certainly no more, possibly rather less, courageous than the numerous operations performed daily throughout the country in which cancer-bearing lymphatics may be cut across and the disease further disseminated. Radium, with its selective action on malignant cells, is more precise and much more delicate than the scalpel, and its influence can be carried further. Clearly, if the disease has already been disseminated to other parts of the body, radium implantation can be no more curative than operation, even though it be gentler in its action. But can, in this event, even a radium-bomb be expected to work the miracle? The disease may be demonstrable *simultaneously* in mediastinum and cervical and lumbar spine, and it is difficult to believe that any method of treatment can be curative other than some therapeutic agent introduced into the circulation.

I fully agree with you that it is "rather much to expect that any implantation of radium tubes can cope satisfactorily with advanced disease." I am not aware, however, that any such claim has ever been made. The introduction of radium treatment has not, and probably never will, invalidate the principle so often inculcated by Lord Moynihan and others that successful treatment depends primarily on early diagnosis. Meanwhile, as recently stated in your columns by Mr. H. S. Souttar, work in this particular field in the continental radiological clinics is almost at a standstill. The radium-bombs are at work, but the treatment of carcinoma of the breast has not progressed, and I doubt whether any other radiological method has ever produced a series of results to parallel those obtained with radium needles by the Surgical Unit and myself at St. Bartholomew's. This may sound immodest, but I believe it is true.

Let us by all means look forward to the day when radium in large quantity shall be available everywhere, but in the meantime no useful purpose is served by depreciating present efforts.

I am, Sir, yours faithfully,
GEOFFREY KEYNES.

Park-square West, April 26th, 1929.

To the Editor of THE LANCET.

SIR,—May I, in a few words, support the timely leading article in your last issue and Dr. G. E. Birkett's letter on which it was based? It is a serious misconception, which has captured a considerable section of medical and lay opinion, that the "surgery of access" is a broad and relatively easy way towards the practical solution of the cancer problem. But the burying of radium tubes is faced, as a method, with difficulties such as you have pointed out, and with a double risk in addition, that of causing or aggravating sepsis, and that of setting free cancer cells by the manipulations involved, and so giving rise to metastasis. Regaud has given it as his opinion that where a malignant tumour can be adequately attacked by external radiation, that method should be preferred to surgical implantation.

Your article asks if deep-seated tumours can be adequately treated by external radium. I have shown this in breast cases,[1] and a few weeks ago in New York I heard from Prof. James Ewing of two cases of cancer of the stomach (operated on, found to be inoperable, and proved malignant) at the Memorial Hospital which show neither clinical nor radiological signs of disease after the 4-gramme "radium-bomb" treatment there. No other known method of treatment can show even such temporary results—for these are recent cases, and by no means to be classed as "cures" yet—but such encouraging omens show the great without success. The second casualty officer, who had been qualified for four months, said he was supervising the operation (which he had himself performed almost daily for the last three months), while a dresser conducted it. There was no undue hæmorrhage; the senior casualty officer was called when the case went wrong. Questions were asked by Mr. Douglas Cowburn, the Camberwell coroner, indicating his opinion that the operation took too long, and that a more experienced anæsthetist would have noticed earlier that something was amiss. He explained to the child's mother that death was due to an overdose of ether, though he added that the doctors concerned (who greatly regretted what had occurred) had done everything possible in the endeavour to save its life afterwards. Mr. Cowburn did not, it appears, condemn the practice of permitting dressers to perform simple operations in a teaching hospital, but he described the degree of supervision as unsatisfactory in the sense that the doctors present had so recently been qualified. A verdict of accidental death was recorded.

Public Health Services.

INSTRUCTION IN SMALL-POX.

THE Metropolitan Asylums Board have arranged a course of instruction in the diagnosis and treatment of small-pox, to be held at Joyce Green Hospital, Dartford, Kent. The first demonstration was on May 1st, and the dates and times of the subsequent demonstrations will be notified by the clinical instructor to students attending the class. Further courses will be held from time to time as may be necessary and practicable. The fee for the course, which will consist of three demonstrations, is £1 1s., provided that students who may be receiving, or who may have received during the past six months, instruction in fevers at the Board's hospitals will be permitted to attend without payment of a fee. Students will be conveyed between Dartford Station and Joyce Green Hospital free of charge. Those who desire to attend must satisfy the Board that they are sufficiently protected against small-pox by vaccination or otherwise. Qualified practitioners may attend the demonstrations without any fee. Application to the Clerk to the Board, Victoria Embankment, London, E.C.4.

INFECTIOUS DISEASE IN ENGLAND AND WALES DURING THE WEEK ENDED APRIL 29TH, 1929.

Notifications.—The following cases of infectious disease were notified during the week:—Small-pox, 374 (last week 339); scarlet fever, 1902; diphtheria, 1067; enteric fever, 39; pneumonia, 1287 (last week 1743); puerperal fever, 44; puerperal pyrexia, 93; cerebro-spinal fever, 22; acute poliomyelitis, 4; acute polio-encephalitis, 3; encephalitis lethargica, 15; dysentery, 8; ophthalmia neonatorum, 121. No case of cholera, plague, or typhus fever was notified during the week.

The cases of small-pox were notified from the following 26 counties:—London, 49 (viz., Bethnal Green, 4; Camberwell, 7; Holborn, 7; Islington, 1; Lewisham, 1; Poplar, 2; Shoreditch, 1; Southwark, 1; Stepney, 25); Chester, 2 (Ellesmere Port); Cornwall, 1 (Stratton and Bude); Derby, 36; Dorset, 1 (Sherborne); Durham, 32; Isle of Ely, 1 (Whittlesey); Essex, 69 (of these West Ham, 66); Gloucester, 1 (Dursley); Huntingdon, 3 (Norman Cross); Kent, 2 (Gillingham, Gravesend); Lancaster, 16; Leicester, 3 (County Borough); Middlesex, 4 (Tottenham, 1; Willesden, 3); Northampton, 26 (County Borough); Northumberland, 2 (Tynemouth); Soke of Peterborough, 4 (Borough); Somerset, 1 (Clutton); Southampton, 1 (Farnborough); Stafford, 31 (of these Stoke-on-Trent, 30); Warwick, 2 (Birmingham, Coventry); Wilts, 7 (Swindon); Yorks, West Riding, 46; Flint, 1 (Prestatyn); Glamorgan, 27; Monmouth, 6.

The number of cases in the Infectious Hospitals of the Metropolitan Asylums Board on April 23rd–24th was as follows:—Small-pox, 276 under treatment, 13 under observation (last week 200 and 10 respectively); scarlet fever, 1479; diphtheria, 1752; enteric fever, 14; measles, 119; whooping-cough, 1154; puerperal fever, 21 (plus 7 babies); encephalitis lethargica, 79; poliomyelitis, 4; "other diseases," 54. At St. Margaret's Hospital there were 10 babies with ophthalmia neonatorum.

Deaths.—In the aggregate of great towns including London there were 2 deaths from small-pox, 2 (2) from enteric fever, 58 (1) from measles, 5 (1) from scarlet fever, 96 (37) from whooping-cough, 39 (11) from diphtheria, 65 (18) from diarrhœa and enteritis under two years, and 161 (32) from influenza. The figures in parentheses are those for London itself.

The deaths provisionally classified to small-pox were assigned to Manchester (C.B.) and Gillingham (M.B.). No great town reported more than 10 deaths from influenza. Liverpool reported 11 deaths from measles, Newcastle-on-Tyne 6, West Bromwich and Birmingham 5 each. The widely distributed deaths from whooping-cough did not exceed 4 in any large town, except Manchester with 5. The highest figures for diarrhœa are Salford and Blackburn with 4 each.

The number of stillbirths reported during the week was 288 (corresponding to a rate of 38 per thousand births) including 53 in London.

Deaths from Small-pox.—Two cases of small-pox, one from the district of Sale and one from Manchester City, which died in the Manchester Small-pox Hospital, were passengers on s.s. *Tuscania.* Dr. W. StC. McClure, acting medical officer of health for Manchester, tells us that Case 1 was a male, aged 44 years, who landed at Liverpool on April 1st and began to be ill on the 3rd; the eruption appeared on the 5th. He was removed to hospital on the 6th and died on the 10th of confluent hæmorrhagic small-pox. He was vaccinated for the first time on March 31st. Case 2 was a male, aged 34 years, who landed at Liverpool on the 1st, began to be ill on the 4th; the eruption appeared on the 6th. He was removed to hospital on the 7th and died on the 14th of confluent hæmorrhagic small-pox. He was vaccinated in infancy, one mark ¾ square inch, and was revaccinated successfully on March 31st.

The Services.

ROYAL NAVAL MEDICAL SERVICE.

Surg. Rear Admiral E. Sutton is placed on the Retd. List at own request.

Surg. Lt.-Comdrs. J. Wylie and H. L. Douglas to be Surg.-Comdrs.

The following appointments have been notified:—Surg. Lt.-Comdrs. (D.): C. Williams to *Greenwich*; R. R. Adams to *Ganges*; D. Paterson to *Pembroke*; and W. E. A. Sampson and M. F. Hopson to *President*, for three months' post-graduate course.

Surg.-Lts. (Short service): T. W. Froggatt, G. Phillips, and C. B. Nicholson transferred to Permanent List.

ROYAL ARMY MEDICAL CORPS.

MILITIA.

Maj. L. A. B. Moore retires on attaining the age limit.

TERRITORIAL ARMY.

Col. C. R. White to be Hon. Col. R.A.M.C. units, 53rd (Welsh) Div.

Maj. W. T. Briscoe resigns his commn. and retains his rank, with permission to wear the prescribed uniform.

Maj. A. F. Hewat resigns his commn.

Capt. G. Sparrow (late R.A.F.) to be Capt.

Lt. E. A. Wilson to be Capt.

2nd Lt. C. R. L'E. Orme, from Gen. List (T.A.) to be Lt.

R. Anderson to be Lt.

TERRITORIAL ARMY RESERVE OF OFFICERS.

Maj. (Bt. Lt.-Col.) C. H. Lindsay resigns his commn. and is granted the rank of Col., with permission to wear the prescribed uniform.

Lt. D. L. Greig from the Active List to be Lt.

INDIAN MEDICAL SERVICE.

Capt. Sankarankoil Chidambaranatha Alagappan to be Maj.

Lt.-Col. W. M. Anderson retires.

Maj.-Gen. W. H. S. Nickerson, late R.A.M.C., has been selected for appointment as Director of Medical Services in India in succession to Maj.-Gen. Sir Walter H. Ogilvie, I.M.S., who will retire in September.

general condition deteriorates, as shown by increasing hypotension and a persistence of the ketosis. I have obtained an almost miraculous recovery in such a case by a suitable dose of insulin, followed in one hour by the intravenous injection of 600 c.cm. of gum saline containing 30 g. of glucose.

I am, Sir, yours faithfully,
H. E. MANSELL, M.R.C.S.
Hastings, April 29th, 1929.

THE INJECTION TREATMENT OF VARICOSE VEINS.

To the Editor of THE LANCET.

SIR,—Prof. Archibald Young's letter in your issue of March 2nd (which has just reached me) must surprise a large part of the medical world. The annotation to which he takes exception to my mind undoubtedly reflects what the vast majority of us who have treated varicose veins by injection feel about this new treatment. Referring to the annotation, Prof. Young says "This is a general statement that should hardly be made without a simultaneous presentation of the proofs upon which it is based." If he had been present as I was at the conference at the Royal Society of Medicine in London last year, when the late Prof. Sicard of Paris and his assistants reported more than 300,000 injections given without a fatality, or even a severe complication, I think he would not condemn a line of treatment which, on his showing, he has not even attempted to try. The injection treatment of varicose veins has come to stay. It is a safe treatment which all medical men can carry out in their consulting rooms with the best possible results if the cases are properly selected. The avowed purpose of the method is not obliteration of the lumen of the vein by the production of thrombosis. Obliteration will not occur unless the injected fluid comes into free contact with the vein wall, giving rise to local irritation which causes the intima to swell and proliferate all round (with or without an actual thrombus), glueing the walls of the vein together. In this part of the world we have been using sclerosing injections for six years or more with no untoward consequences. It is economical for the patient, both in time and money. It is far safer than an operation; the patients are delighted, and the medical men are satisfied. I personally sclerosed my own veins last year with the fullest confidence.

I am, Sir, yours faithfully,
S. M. WELLS, F.R.C.S. Edin.
Valparaiso, Chile, South America, March 27th, 1929.

OPEN-AIR TREATMENT OF SUBNORMAL CHILDREN.

To the Editor of THE LANCET.

SIR,—Dr. Elizabeth Miller's interesting article in your issue of April 20th on the experiment which the Huddersfield Education Authority has undertaken in the open-air treatment of "subnormal" children, prompts me to inquire what percentage of the children selected for such treatment are suffering from actual tuberculous toxæmia, and not merely from debility due to poor home environment and hygiene. It is stated that the children selected suffer mostly from anæmia, malnutrition, deficient muscular tone, and lassitude; but are not such symptoms typical of early tuberculous infection—so often miscalled the "pre-tuberculous" phase—which would naturally respond to the regimen outlined in her article? It would be interesting to know whether these children are subjected to tuberculin tests.

In Southfield Sanatorium Colony under the Royal Victoria Tuberculosis Trust numbers of such "subnormal" children are treated along sanatorium lines, and the results amply justify the claims made by Dr. Miller, the improvement in the child's condition being almost invariably rapid and dramatic. The great majority of such children, however, give a positive tuberculin reaction, and are regarded as definitely suffering from the effects of tuberculous infection.

It is possible, therefore, that the Huddersfield Education Authority has—perhaps unwittingly—been among the first of public bodies to establish the system whereby the problem of tuberculosis may be thoroughly successfully tackled, through increasing the resistance of the "subnormal" child, who is really tuberculised, long before relatively intractable gross glandular or pulmonary lesions have manifested themselves.

I am, Sir, yours faithfully,
D. MELVILLE DUNLOP, M.D.
Southfield Sanatorium Colony, Edinburgh,
April 29th, 1929.

SOLAR DERMATITIS.

To the Editor of THE LANCET.

SIR,—In the leading article on Solar Dermatitis, which appeared in your issue of April 27th, you quote Vallery-Radot's observations on the effect of the mercury-vapour lamp on sun-sensitive persons. The rays emitted by the K.B.B. mercury-vapour lamp vary in wave-length approximately from 2,000 to 5790 Angström units, and it is these rays and not the more slowly vibrating rays of the visible spectrum which are supposed to produce the reactionary erythema and pigmentation of the skin.

But evidence is increasing that the reaction which we call solar dermatitis, occurring in sun-sensitive persons, is not due to the ultra-violet rays, but to rays nearer to the yellow and red rays of the visible spectrum. These are the photosynthetic rays which are employed by the green leaf in converting carbonic acid into carbohydrate. Their dynamic character is constructive in opposition to the ultra-violet rays which are essentially destructive.

In persons liable to solar dermatitis some chemical substance is present in the skin, which substance is activated, or increased in quantity by some of the visible rays of the solar spectrum. This substance, the nature of which is at present unknown, is apparently destroyed by the ultra-violet light.

The following case shows that while improvement may follow ultra-violet radiation the "cure" is only temporary.

Mrs. A. B., aged 60, came under my care for solar dermatitis in May, 1927. The sun-sensitiveness was of recent origin, her first attack being in the summer of the previous year. The parts affected were the face, the backs of the hands, fingers, and wrist, and slightly the fronts of the legs. The lesions were erythematous and urticarial. A 24-hour specimen of urine showed a definite excess of urobilin but no hæmatoporphyrin. The colour of the iris was blue-grey, with brown pigment interspersed at the outer margin. The complexion was sallow. She was 33 days under observation, during which she had 16 exposures to the mercury-vapour lamp. The first ten exposures were at 30 inches from the burner, the shortest interval being 28 inches. The duration of exposure varied from two to five minutes. The temperature of the room was about 21° C. (approximately 70° F.). The face, neck, trunk, upper and lower limbs were exposed to the rays, but no area was re-exposed on two consecutive days. By the 16th day of treatment there was marked improvement in the face and diminution of sensitiveness, for even when the patient had sat in the garden for several hours no solar reaction ensued, except slight swelling of the hands.

On conclusion of the course of treatment the patient obtained relief for a few weeks. I have not seen her since July, 1927, but in a recent letter she informs me that during the following summer she suffered from the same complaint, and again during the present spring.—I am, Sir, yours faithfully,

H. LESLIE-ROBERTS, M.D.
Liverpool, April 30th, 1929.

STUDENTS' BEDS AT BIRMINGHAM.—Two beds endowed out of the amount allocated from the money raised by students of Birmingham University at their last carnival were last week unveiled at the Queen's Hospital.

Parliamentary Intelligence.

NOTES ON CURRENT TOPICS.

LOCAL GOVERNMENT (SCOTLAND) BILL.

IN the House of Lords on April 24th, on the motion for the third reading of the Local Government (Scotland) Bill,

Lord **ARNOLD** said this Bill had aroused intense opposition in Scotland. It would lead to administrative chaos, and before long amending legislation would be necessary. The Marquess of **SALISBURY** (Lord Privy Seal) said that the opposition to the Bill was not so great as Lord Arnold had suggested, and as a result of the concessions which had been made by the Government the opposition had become inconsiderable. The Bill was read the third time.

On April 26th the House of Commons considered the Lords' amendments to the Local Government (Scotland) Bill. All the amendments were agreed to with the exception of the amendment providing that on a vacancy arising in the office of medical officer of health or sanitary inspector of a small burgh the corresponding officer of the county should ipso facto become the officer for that burgh. This amendment was disagreed with.

SCHOOL MEDICAL SERVICES.

In the House of Commons on Tuesday, April 23rd, Lord **EUSTACE PERCY** (President of the Board of Education), speaking on the Vote for the salaries and expense of the Board of Education, said that to complete a balanced scheme of education they must give a more natural and normal place in the structure to two types of school which had hitherto stood rather outside our elementary school system—the special school and the nursery school. As regarded the special school, a recent report of the Committee appointed by Sir George Newman had indicated certain defects in the methods of dealing with mentally deficient children. He (Lord Eustace Percy) had always felt these defects very strongly. He had been somewhat criticised for waiting for this report before deciding upon his policy in regard to schools for mental defectives, but he believed that the Committee's work would enable them to make a more comprehensive and varied provision for the needs of such children within the general school system than had been possible on the basis of a procedure of medical certification, which had tended to divide retarded children into two fixed and somewhat artificial categories. The nursery school presented a very different problem, but it was also a subject on which they all needed to clarify their views by thorough investigation. He frankly admitted that he had left this problem in the stage at which he had found it—that of isolated experiments. Those experiments had not been unfruitful. They had, for instance, led the Board to modify its views on certain points, such as the size of nursery schools, but they could not be content either with the present rate of progress or with any of the proposals which had recently been put forward on this subject, which seemed to him to amount to little more than a multiplication of isolated experiments. The time had come when this, their one remaining administrative problem, should be brought into the focus of a settled policy and, as recently announced, the Board of Education proposed to conduct a comprehensive inquiry with that object.

Scottish Education Estimates.

The Education Estimates for Scotland were subsequently discussed.

Mr. D. M. **COWAN** expressed satisfaction that recently an educational research committee had been set up in Scotland. That committee, he said, received its income in equal parts from the teaching profession and the school authorities, and last year it had at its disposal something like £1500. The committee was composed of representatives from the two bodies named, from the universities, the technical colleges, and the medical profession. Scotland in this matter of research had been perhaps rather backward for a long time; she was, perhaps, living somewhat on her tradition, and it was therefore all to the good that she had now this enthusiastic body devoting itself to the study of educational methods and the child mind. The object of the committee would be not only to provide a good educational course for the normal child, but to find out how the backward child could be specially dealt with. It would be impossible for the Scottish Education Department to become a direct party to the Research Committee, because it might be thought in that event that they were bound by the findings of the committee.

Nutrition of School-children.

Mr. **JOHNSTON** said that in the report of the Scottish Education Department it was admitted that the nutrition of over 6 per cent. of the school-children examined by the school medical officers was below the average. That was due to hunger. What did the department intend to do to see that this 6 per cent. were sufficiently fed at school? Within the last ten years things had gone back in this respect. Ten years ago the onus was indirectly on the education authority, but now the education authority only stepped in when private charity had failed. Even then they might make arrangements with the poor-law authorities, so that it was only in the last resort that the education authorities intervened to see that a child was in a physical condition to receive the education provided. The average cost of a school-child was 22s. per week, and he asked why they should not spend the extra two or three shillings which would ensure that the amount spent on education was wisely spent? If they did not attend to a child's physical condition in its school years they would have to pay for it afterwards in the cost of sanatoria, hospitals, and other public institutions. He urged that the 6 per cent. of school-children who were under-nourished should be immediately looked after by the authorities. The question of medical inspection of school-children was very briefly dealt with in the report of the department. Even in such reference as was made they were referred to the tenth annual report of the Scottish Board of Health, and on turning to that report they found that 73 per cent. of the children attending schools suffered from defective teeth. The dental services were inadequate. Then there was rickets—a poverty disease—and defective eyesight, which amounted to 5 per cent. and was still growing. All these facts did not seem to merit any encomiums on the work of the Education Department so far as the health of the school-children was concerned. Sir George Newman in a book recently published by the Health Department, showed, distinctly and clearly, how, for an almost infinitesimal public expenditure, and by taking the right kind of diseases first, they could wipe away great blocks of pain and disease in the public life of the nation. Yet the department were actually going backwards so far as the feeding of school-children was concerned. Many of the schools were designed and built many years ago, and in his (Mr. Johnston's) opinion, a very large amount of the children's troubles arose directly from bad heating arrangements and bad ventilation. Until those arrangements were changed they were not likely to wipe out a considerable proportion of children's troubles.

Reply to the Debate.

Major **ELLIOT** (Under Secretary for Scotland), replying to the debate, said that the school accommodation in Scotland had been considerably enlarged in the past few years. With regard to clinics, it was obviously a mistake to mix up sound and sick school-children and defective children with normal children, and to create an educational institution with clinical facilities of one kind and another. There was every reason to believe that with the unification of the activities of the local authorities it would not be necessary to overcrowd the educational institutions with school clinics, while a street or two away, or it might be only across the street, there were facilities for carrying out these medical examinations in buildings designed for the purpose, where it could be done without trenching on the all too inadequate provision available to teachers for carrying out the main purposes of the school. Everybody agreed that it was a desirable thing to unify and amalgamate the health services. The break between the school health services and those of the local authority was undoubtedly one of the blots on our educational system which the Local Government (Scotland) Bill would remove. He was sure there would be a very great improvement as the result of the working of that Bill. He would report to the Secretary of State for Scotland that the Committee in its discussion that night considered that greater attention should be paid to the physical condition of school-children.

The debate on the Vote was adjourned.

COLONIAL MEDICAL SERVICES.

On Tuesday, April 30th, the House of Commons went into Committee on the Civil Service Estimates, Mr. D. **HERBERT** in the chair.

On a vote for the salary and expenses of the Colonial Office, Mr. **AMERY** (Secretary of State for the Dominions), speaking of colonial research work, said that important as animal and plant health were, human health was of even greater importance, and the Colonial Office was not only an administrative office, but very essentially a Ministry of Health for the tropical world. In that matter there had been a great stir on the face of the waters throughout the Colonial Empire. In every direction governors and administrators had shown the greatest enthusiasm, often splendidly supported by their wives, in the matter of maternity and child welfare and in improving the health conditions of the people. Everywhere the position was improving. For instance, the creation of the large electric power scheme, which was carried out in a malarial jungle, had involved no appreciable sickness among the body of 4000 workers, a condition of affairs that would have been incredible a few years ago.

Dr. **Vernon Davies**: Thanks to the medical profession.

Mr. **Amery** said that in every direction educational institutions had been increased. To-day the great hospitals on the Gold Coast and at Singapore were unrivalled in the tropical world. Ceylon had 100 hospitals and something like 8000 beds. Malaya had 25 travelling motor dispensaries and two motor-boats, which, in a year, treated 150,000 cases. There was a Medical College at Singapore, an institution calculated to be of immense importance to the whole of the Eastern colonies, and it was hoped shortly to establish something of the same sort in West Africa. In many of these departments of research they were greatly indebted to the Rockefeller Foundation for the assistance which they had given. At headquarters greater attention in these matters had been reflected in the change in organisation. In 1926 an adviser on medical questions was appointed at the Colonial Office and the appointment had now been made permanent. There was a Colonial Advisory Committee on medical and sanitary questions, and in 1927 there was added a special Colonial Medical Research Committee, and they had also received the coöperation of such institutions as the London and Liverpool Schools of Tropical Medicine. Not the least important matter in this connexion was the training of native medical staffs. They hoped to increase that work which had grown to a remarkable extent in the last five years all over West Africa, and to build up an increasingly high degree of medical training so as to enable the natives to qualify for the actual conduct of the treatment of these cases. No less essential was the development of education in questions of hygiene among the general mass of the population.

Mr. **Amery** gave the names of the Committee which he had appointed to consider the existing system of promotion in the Colonial Office and public services of Dependencies not possessing responsible government. The Committee would include Dr. **Drummond Shiels**, M.P.

The vote was agreed to.

THE LONDON LOCK HOSPITAL.

On the motion for the adjournment,

Mr **Pethick-Lawrence** called attention to the management of the London Lock Hospital. He said that the Minister of Health had admitted in reply to questions that the Report of the Committee of the Inquiry showed that very considerable changes in the management of the hospital were desirable. The right hon. gentleman, however, had refused to publish the Committee's report and had stated that the Board of the Hospital were making very considerable changes. In his (Mr. Pethick-Lawrence's) view, reforms at the Hospital could not be carried out except by a reconstituted Board of Management and a change in the personnel of the Hospital staff. It was 10 years since the action of the Board was first called in question, and the first body of responsible women found it necesssary to resign because their protests remained unanswered. All that time the Board had made no important changes. The promises of the Board were not good enough. Apart from the changes in the management and personnel to which he had referred it was also necessary that the report of the Committee of Inquiry should be published so that public confidence might be restored.

Mr. **Chamberlain** (Minister of Health) said that he wished to remind the House of his position in this matter. This was a voluntary hospital. It was not an institution over which he had any authority by law, and he only came into the matter because in consequence of certain publicity which had been given to the charges made against the Board, the Board requested him, as an impartial and independent person, to appoint a small Committee to inquire into the charges. In asking for that inquiry, the Board made it a condition that it should be a private inquiry, that the evidence should be treated as private; and it was on that condition that the Committee was appointed and evidence was given before it. It was quite clear, therefore, that in no circumstances could the evidence given to the Committee be published. He had no personal knowledge of the circumstances which led to the charges which had been alluded to; his concern was rather that of a person who desired to see that the interest of the public in London were protected. This Hospital, which was the only one of its kind in London could, if properly conducted, perform a great service and one which no other institution was capable of performing. He was not concerned to defend the members of the Board, nor to pursue any vendetta against them. Some of the delay which had taken place was due to the fact that the Chairman of the Board had been in very bad health, and had not been able to give continuous attention to the matter, which required concentrated attention. A Board, faced with recommendations which involved a number of suggestions for the alteration of the management and of the whole system on which the Hospital was run could hardly be expected to f[illegible] proposals to carry out those recommendations in the course of one or two meetings. It was only reasonable that they should take adequate time to examine thoroughly all possible alternatives and try to find a solution of what must have been a very difficult and embarrassing situation for them. If he felt that the Board was not facing up to the situation and was disposed to go on as it had before, and to take no serious account of the important suggestions which had been made in the report, he would not have hesitated to publish the report as a means of bringing pressure upon them through public opinion. But he had felt all along that that was a course which he ought not to take unless he felt convinced that it was really necessary to bring about the results desired. The report, after all, did not charge the members of the Board with any moral obliquity, any dishonesty, or any financial irregularity; but it certainly did indicate that the administration of the Board, in parts, might well be improved. The publication of the report would draw public attention to the Hospital in a way which could hardly fail to have a serious effect upon the working of the Hospital itself. The first result must inevitably be a reduction in the public contributions to the Hospital, which had already suffered to some extent. The public discussion of the report would present difficulties to the Board in obtaining the services of the staff—not merely of the medical staff, but particularly of the nursing staff. He had very good reason to suppose that the reconstitution of the Board did form a part of the proposals which he expected to have in his possession before very long. He had in contemplation some further steps which he did not feel at liberty to discuss in public, but which might well further assist towards a satisfactory solution. He still reserved to himself the right to take a decision and publish the report if he was not satisfied with the administration of the Hospital.

HOUSE OF LORDS.

THURSDAY, APRIL 25TH.

Road Vehicles Bill.

Viscount **Cecil of Chelwood**, in moving that the House go into Committee on the Road Vehicles Regulation Bill, said that although the Select Committee which had considered the Bill recommended that it be not proceeded with, he thought that with amendments, which he was prepared to move, he would be able to convince their lordships that the Bill was entitled to further examination by them. The reason given by the majority of the Select Committee for coming to the conclusion that the Bill should not be proceeded with was that it had little chance of success. He thought that the fact that the Parliamentary chances of the Bill were remote ought not to make any difference to their lordships in dealing with the measure. The position as regarded road accidents had become even more serious than it was last autumn when he raised the matter before their lordships. The fatal accidents last year had increased 20 per cent., and this was not accounted for by the increase in the number of cars on the road, which only amounted to 5 per cent. The non-fatal accidents had also increased to a very large extent. The evil was one which urgently called for attention, and if the proposals in the Bill would do anything to mitigate that evil, whether they passed into law or not, it was the duty of their lordships to pass them.

Lord **Sandhurst**, in moving the rejection of the Bill, said that the Select Committee, of which he was a member, was impressed with the belief that had they tried to amend the redrafted Bill they would have failed to present anything like an uncontroversial measure that might have had a chance of passing into law during the present session.

Lord **Buckmaster** supported Lord Cecil's motion.

Earl **Russell** said that it would be of no use to carry the Bill any further as it was not susceptible of useful amendment.

Lord **Danesfort** said he thought that the Bill with amendments which their lordships might make would be extremely valuable.

The Earl of **Birkenhead** said everyone acquainted with the present state of Parliamentary business knew that this Bill had not the slightest chance of becoming law in the present Parliament.

The Marquess of **Londonderry** (First Commissioner of Works) said that the Government had opposed the Bill on the second reading on two very serious grounds. First of all they considered that the proposals were hardly of the character called for by the present traffic situation. Their second main objection was that the Royal Commission on Transport, presided over by Sir Arthur Griffith-Boscawen, was already examining the questions dealt with by the Bill, and it would obviously be premature and undesirable to proceed with legislation pending the report of that Commission. The Government fully recognised, however, the [illegible]cy of the problem of road traffic regulation and were not careless of the loss of life, which was the truly deplorable feature of present-day road traffic; but it must also be recognised that the problem was one of immense complexity. He could assure Lord Cecil that though the Bill might be dropped his efforts to arose the public to a sense of the urgency of this question had not been in vain. If the present Government were returned to power after the General Election they would produce a Bill dealing with the matters concerned in Lord Cecil's measure, fortified and strengthened as they would then be by the consideration of the recommendations of the Royal Commission. He asked Lord Cecil not to press further consideration of the Bill.

Viscount CECIL said that he could not feel that he would be doing any good by consenting to the withdrawal of the Bill.

Viscount CECIL's motion to go into Committee was defeated by 49 votes to 6.

Battersea Power Station.

Lord JESSEL called attention to the menace to the health and amenities of London by the erection of the Battersea Power Station and moved for papers. He said the proposed station would be close to Battersea Bridge and within 300 yards of Westminster. It would be the second largest in this country. It was expected to consume some 800,000 tons of coal. The noble lord drew attention to a letter which had appeared in the *Times* signed by very important and influential people. That letter drew attention to the corroding nature of the sulphurous fumes from the station, and added that as the prevailing wind in London was from the south-west the normal flow of fumes from the Battersea station would take a line over the Tate Gallery, Lambeth Palace, St. Thomas's Hospital, the Houses of Parliament, and other important buildings. The letter went on to say that it was doubtful whether any proper provision could be made to secure the prevention of sulphurous fumes in the atmosphere. He hoped that the Government would make a move in the matter in order to prevent the erection of the station. If they did not do so, no doubt the public bodies who were opposed to the project would apply for an injunction. The only promise they had so far obtained from the Government was that the Government chemist should be the arbitrator as to whether proper precautions had been taken or not.

After further discussion,

The Marquess of LONDONDERRY said that the Office of Works were very keenly alive to the suggestions that had been made by Lord Jessel and in the Press signed by very influential names. He could assure the noble lord that with the advantages at their disposal and the experts that they had the privilege of consulting it was not likely that they were proposing to hand over any of their responsibilities or not to discharge them to the best of their ability. The health of the population was a very important matter, and Lord Jessel could be satisfied that a project of this kind would not be allowed to go forward unless the Minister of Health was satisfied that there was no danger. As a result of scientific research smoke and grit need no longer be a nuisance to the public. The erection of this station would eliminate three other stations, and the reduction of sulphur fumes due to coal fires was calculated to be no less than 30 per cent. By electricity being made available to the population in London the consumption of coal in a great number of houses would also be reduced. Only one-third of the full scheme has been at present authorised, and he would give an assurance to Lord Jessel that the further extension of the generating station to the remaining two-thirds would not be undertaken unless it was clearly understood and agreed by the authorities that there was no danger from the health point of view, or from the destructive point of view, which did in the minds of many people follow as an effect of sulphur fumes. The matter was engaging the full attention of the Minister of Health, the Minister of Transport, and himself as First Commissioner of Works. Unless they were satisfied on the advice of the Government chemist and of the Department of Scientific and Industrial Research that there was no danger the full scheme would not be completed.

Lord JESSEL said he thought the safeguards given by Lord Londonderry were much more ample than those given by the Minister of Transport in the House of Commons. He was grateful for the assurances.

After further discussion, Lord JESSEL withdrew his motion for papers.

TUESDAY, APRIL 30TH.

Pharmacy Bill.

Lord DESBOROUGH, in moving the second reading of the Pharmacy Bill, explained that it was designed to secure reciprocity in regard to the registration of qualified pharmacists between Great Britain and Northern Ireland.

The Bill was read a second time.

Age of Marriages Bill.

Lord BUCKMASTER, in moving that the House go into Committee on the Age of Marriages Bill, said that the measure had been referred to a Select Committee who had unanimously reported in favour of a change in the legal age of marriage rendering a marriage void between persons either of whom was under the age of 16. He said that if the House agreed to his motion he would move amendments providing that if a man was charged with having unlawful connexion with a girl under 16 it should be a defence if he could show that when he married the girl he had reason to believe that she was 16 years of age; and also that in the case of a marriage being declared void under the Act, it should be lawful for the woman to apply for maintenance for a child born after the marriage, such child then becoming illegitimate within 12 months of the marriage being declared void.

The Marquess of SALISBURY (Lord Privy Seal) said that the Government were in favour of the Bill and were anxious that it should become law. He wished to point out, however, that at this stage of the Session it was impossible to pass the measure unless by general consent. The Government had no objection to the insertion of the amendments referred to by Lord Buckmaster, subject to redrafting on the Report stage.

Lord BUCKMASTER's motion was agreed to.

The amendments were agreed to and the Bill passed through Committee and was reported to the House.

HOUSE OF COMMONS.

WEDNESDAY, APRIL 24TH.

New Treatment for Epilepsy.

Sir BERTRAM FALLE asked the Minister of Health if he could give any information as to a new treatment of epilepsy by Prof. Fitzsimons, of Port Elizabeth, which had now been tried for a considerable period; and the results, if any, of the treatment.—Mr. CHAMBERLAIN replied: I understand that this is a treatment with a preparation from the venom of the Puff adder and the Cape cobra. I have no exact information of the results of the treatment, but according to an article in the *Journal* of the Medical Association of South Africa of Nov. 24th, 1928, p. 598, there is no reason to believe that the results are superior to those obtained by the use of the more common remedies.

Woman's Death at Sudbury.

Sir CHARLES OMAN asked the Minister of Health whether he had received any information as to the recent inquest at Sudbury where the doctor who gave evidence in the case stated that it was one of starvation; what were the circumstances; whether the deceased applied for medical or other out-relief; whether any of the officers of the guardians or the guardians were cognisant of the deceased being in need; if so, whether and when the officer or the guardians offered such relief: and, if not, why not.—Mr. CHAMBERLAIN replied: I have received a newspaper report of this inquest and a copy of a report made by the relieving officer to the clerk to the Sudbury Guardians. The deceased was 76 years of age. She was in receipt of an old age pension of 10*s.* a week and a weekly parcel of food, value 5*s.*, from a charitable fund. At the date of her death 14*s.* 2*d.* in cash and an adequate supply of fuel and food was found in the house. The deceased was a very independent old lady and would not let anybody do anything for her. The jury's verdict was that death was due to heart failure accelerated by the cold weather, following starvation and self-neglect. The deceased had been an inmate of the Sudbury Poor-law Institution, but was discharged at her own request on April 24th, 1927, and no application for relief had been made by her since that date. As regards the remaining parts of the question, it will be seen from the information given above that the deceased was not lacking in food, fuel, or shelter. I concur in the view reported to have been expressed by the coroner at the inquest, that it did not appear that anyone could be called in question for having neglected the deceased.

Smoke Abatement By-laws.

Sir ROBERT THOMAS asked the Minister of Health the number of by-laws made, and the number applied for, under Section 2 (1) of the Public Health (Smoke Abatement) Act, 1926; the number of by-laws made or applied for under Section 5; the number of local authorities combining for the purposes of the Act as under Section 6; and the extent to which local authorities had made use of the powers to conduct researches as under Section 10.—Mr. CHAMBERLAIN replied: Fifty-one by-laws have been made and confirmed by the Minister under Section 2 (1) of the Public Health (Smoke Abatement) Act, 1926, and 37 more are under consideration; no application has been received for the confirmation of any by-laws under Section 5. One committee has been formed, so far as I am aware, with administrative powers under Section 6, representing two authorities; five regional advisory committees have been formed representing some 300 authorities. As regards the last part of the question, I have no exact information, but I am informed that 40 local authorities are coöperating in systematic observations of the extent of atmospheric pollution, and 33 authorities are contributing to the cost of the central services of the Department of Scientific and Industrial Research for supervising and coördinating the observations and towards research for improving the methods of making these observations.

Thursday, April 25th.

Empire Cancer Campaign and Radium Appeal.

Lieut.-Colonel Fremantle asked the Minister of Health whether the *British Empire Cancer Campaign* was consulted before the Government decided its action with regard to the proposed radium appeal; and whether the campaign, as the principal association for the promotion of cancer research, would be asked to undertake the appeal to the public for funds.—Mr. Chamberlain replied: The answer to both questions is in the negative. While I appreciate the work being done by the British Empire Cancer Campaign in regard to cancer, I should hesitate to accept the estimation of its position in regard to cancer research contained in my hon. and gallant friend's question.

Children in Poor-law Institution.

Mr. Bellamy asked the Minister of Health whether he was aware that there were 10 young children maintained in the Market Bosworth Poor-law Institution, and that there was no proper accommodation for these children, and that they could not be separated from adult and weak-minded inmates; whether he would state the longest period during which any one of these children had been detained in this institution; and whether he would make representations to the board of guardians on the matter.—Mr. Chamberlain replied: I am already in correspondence with the guardians of the Market Bosworth Union concerning their failure to comply with the requirement of Article 4 of the Poor-law Institutions Order, 1913, that children between the ages of 3 and 6 shall not be retained in the institution for a period exceeding six weeks, except on medical grounds. The number of children so detained is at present eight.

Home Treatment of Panel Patients.

Mr. Thurtle asked the Minister of Health if he was aware that, at the inquest proceedings recently on the death of a Shoreditch man named Daniel Fitter, the coroner who presided commented on the inadequacy of the home treatment of this panel patient and of panel patients in general; and if he would inquire into the home treatment given to insured persons.—Mr. Chamberlain replied: I have seen Press reports of this case. Insurance practitioners are required by their terms of service to visit and treat patients whose condition so requires at any place within the districts in which the practitioners have undertaken to visit patients; and any complaint that a practitioner has failed to visit a patient when necessary should be made in the first instance to the local insurance committee, who must have it investigated. I do not think the present case affords sufficient reason for a general inquiry such as the hon. Member suggests.

Small-pox on the "Tuscania."

Lieut.-Colonel Fremantle asked the Minister of Health if any cases of small-pox had been notified during the past week from passengers or crew on the steamships *Tuscania* and *Mashobra*, or from contacts with such persons; if any further deaths had occurred during the week; and what was the vaccination history of the fatal cases that had occurred hitherto.—Mr. Chamberlain replied: According to the information at present available, two cases of small-pox have been notified during the past week from the *Tuscania*. No further deaths have occurred and no case of small-pox has been reported from the *Mashobra*. Information as to the vaccinal history of the fatal cases from the *Tuscania* is not yet available.

The Royal Veterinary College.

Viscount Sandon asked the Minister of Agriculture whether he had yet decided on any action to place the Royal Veterinary College on a modern footing.—Mr. Guinness replied: No, Sir. I am unable to come to a decision on this question pending the receipt of the report of the committee, to which reference has previously been made.

The Radium Appeal.

Mr. Robert Morrison asked the Prime Minister what guarantees the Radium Committee had received that the proposed purchase of 20 g. of radium by voluntary and State funds could be effected at a lower price than the existing price for Great Britain of £12,000 per gramme.—Mr. Chamberlain replied: The subcommittee were not in a position to secure any guarantee that 20 g. of radium bought through a single agency would be cheaper than very much smaller amounts bought by numerous purchasers. But the hon. Member will find their reasons for their opinion on the point in paragraphs 71 and 82 of their report.

Vaccination of Visitors to France.

Lieut.-Colonel Fremantle asked the Secretary of State for Foreign Affairs the requirements with regard to vaccination of visitors proceeding from this country to France; whether these requirements were to continue throughout this year and in future; and whether these matters would in future be arranged through the International Committee of Public Hygiene, at Paris, or through the Health Organisation of the League of Nations, at Geneva.—Mr. Locker-Lampson (Under Secretary for Foreign Affairs) replied: The regulations with which travellers proceeding from this country to France now have to comply provide that: (1) all persons in possession of certificates to the effect that they have been vaccinated within the last five years and not more recently than ten days will be allowed to land without hindrance; (2) those without such certificates will be required to fill in a sanitary passport, giving their names and addresses and their destination, so that they may be subject to medical supervision during the next 14 days; (3) there will be no compulsory vaccination on disembarkation. I understand that at Dieppe holders of certificates are also being asked to submit their arms for medical inspection. At Havre the special regulations introduced by the Mayor and announced in the Press are still being enforced. With regard to the second part of the question the length of time which these regulations will remain in force must necessarily depend upon circumstances. With regard to the third part of the question, it is not, in the opinion of His Majesty's Government, possible to leave the details of administration in such matters to an international body. I would, however, draw the hon. Member's attention to the fact that the French Government have acted in the present case in accordance with Article 42 of the International Sanitary Convention signed at Paris on June 21st, 1926.

Deaf and Dumb Children.

Mr. Thomas Williams asked the President of the Board of Education whether his department admitted any special obligation to assist deaf and dumb children after they left school to secure employment; if so, what proportion of such children secured employment immediately, and how many remained unemployed; and would he consider the advisability of inquiring fully into this class of case with a view to ensuring that employment at reasonable wages should be available for all persons suffering from these disabilities.—Captain Wallace (Lord of the Treasury) replied: The function of the Board of Education in the matter is to secure that the education and training of deaf children shall be such as to fit them as far as possible to become independent self-supporting members of the community. The hon. Member will find full information on the training and placement of deaf children in the chapter on the deaf child (Appendix B.) in the report for 1927 of the Board's chief medical officer. I would refer him particularly to Section 13, which deals with the placement of the deaf child in work on leaving school and details the different agencies concerned with placement. My right hon. friend will consider whether it will be advisable to inquire further into this matter.

Monday, April 29th.

Vaccination and Small-pox at Bombay.

Captain Bourne asked the Under Secretary of State for India whether the Government of India proposed to take any steps to prevent unvaccinated persons embarking for Europe from Bombay during the present epidemic of small-pox in that city; and, if so, if he would state the nature of such proposals.—Earl Winterton replied: The Government of India reports that circulars were issued to shipping companies by the Port Health Department, Bombay, advising the vaccination of all passengers and crews of vessels leaving Bombay, except persons recently vaccinated, and it is understood that this advice is being followed. The latest *available figures, those for the week ending April 6th, show* that small-pox has been on the decline in Bombay city since the middle of March, the number of cases having fallen from 142 during the week ending March 16th to 86 during the week ending April 6th.

Dr. Vernon Davies: Are we to understood that vaccination is advisory and not compulsory?

Earl Winterton: At present I understand that the local authorities which deal with the matter have issued circulars to the companies advising vaccination of their passengers.

I cannot without reference remember whether they have power to make vaccination compulsory. If they have such power, and it is advisable to do so, no doubt it will be enforced.

TUESDAY, APRIL 30TH.

Widows and Orphans and Sickness Grants.

Mr. ROBINSON asked the Minister of Pensions the number of applications received from widows and orphans for sickness grants and the number granted and their cost in 12 months to the last convenient date; if any steps were taken to inform these dependents of men who gave their lives for the country that they were eligible for assistance during periods of ill-health; and, if not, if he would arrange that the widows and the guardians of orphan children should be notified by the Ministry that they were eligible for such assistance.—Sir WILLIAM COPE replied: The number of applications received by the Special Grants Committee during the year ended Dec. 31st last was 494 and in 74 of these cases the Committee were able to make grants at a a cost approximately of £430. The provision for sickness grants, as made in 1924, was designed for cases of a very exceptional character and was subject to specific limitations. Any general advertisement of the grant in the manner proposed would only serve to give an erroneous impression of its character and would lead to disappointment.

Small-pox on the "Tuscania."

Sir BASIL PETO asked the Minister of Health whether there was any quarantine station at the port of Liverpool or any quarantine ship; and, if so, why the s.s. *Tuscania* was not placed in quarantine or the passengers transferred to the quarantine ship when it was found that the ship had small-pox patients on board.—Sir KINGSLEY WOOD replied: The answer to the first part of the question is in the negative. As regards the second part, the measures taken later at Liverpool on the arrival of s.s. *Tuscania* were in accordance with the procedure laid down in the International Sanitary Convention of 1926.

Sir BASIL PETO asked whether Sir Kingsley Wood was aware that in the absence of any quarantine station and ship the crew and passengers were distributed all over the country; and if he was aware that at East Ham and West Ham 24 cases of small-pox arose from contact with a steward from the *Tuscania* who had seven or eight children attending an elementary school at Leyton-road, one of the largest elementary schools in that district?

Sir KINGSLEY WOOD: Yes, Sir. The Minister of Health and I have answered several questions on this matter, giving an exact account of what has taken place. Obviously, however, the conditions which have to be complied with are those of the International Sanitary Convention; but the real lesson of the whole affair is the necessity for vaccination.

Sir F. HALL asked whether, as Sir KINGSLEY WOOD had admitted that vaccination was the method that ought to be adopted, the Government contemplated bringing in a measure to enforce vaccination?

No reply was given.

Disposal of London Refuse.

Sir ALFRED KNOX asked the Minister of Health if he would send down an official from his Department to report on the system of disposal of London refuse at Little Britain, in Middlesex, and at Iver, in Buckinghamshire, of which constant complaint had been made and which was such as to cause danger of an epidemic.—Sir KINGSLEY WOOD replied: Mr. Dawes, the Public Cleansing Inspector of the Department, has recently inspected refuse tips at Little Britain and Iver, and the conditions there are described in his report on the public cleansing service of London which was published in March. My right hon. friend has appointed a Departmental Committee to consider that report and to recommend what measures should be taken on it. In the meantime my right hon. friend is making further inquiries into the circumstances at Iver where he understands a new tip has been started.

BATH ROYAL UNITED HOSPITAL.—The buildings of this hospital in the centre of the city are to be used as a municipal technical college, and the hospital is to be transferred to the building at Combe Park recently vacated by the Ministry of Pensions. The City Corporation is paying £30,000 for the old buildings.

PROGRESS OF MIDDLESEX HOSPITAL.—Last year the number of in-patients treated to a conclusion at this hospital was 6271, as compared with 5512 in 1927. Out-patients made more than a quarter of a million attendances. The expenditure was £100,000 and the total income £83,000. Admissions to the Middlesex Cancer Hospital numbered 718, and the number treated to a conclusion 712, as compared with 546 in the preceding year.

Obituary.

FRANK COLE MADDEN, C.M.G., M.D. MELB., F.R.C.S. ENG.

DR. F. C. Madden takes a high place among the many men of English race who have given their lives to the service of Egypt, for he probably did more than any other of his generation to raise the standard of practical surgery and medical education in that country. Modern medicine can play so large a part in improving Egyptian life that the ultimate effect of such work as his is likely to be very large indeed, and his death at Cairo on April 26th at the age of 56 will be deplored not only by those who knew him, but by all who saw the importance of what he had done and was doing.

Born at Melbourne, Australia, Frank Cole Madden was the son of D. A. Madden, of Sydney, and was educated at the Scotch College, Melbourne, and afterwards at Melbourne University, where he distinguished himself as a student. After holding resident posts at Melbourne Hospital in 1894 he came to London to study at St. Mary's Hospital for the Fellowship of the Royal College of Surgeons, which he gained in 1896. In the same year he was appointed resident medical officer at the Hospital for Sick Children, Great Ormond-street, and there came in contact with the late Edmund Owen, then surgeon to the Hospital, whose niece he afterwards married.

Madden started his successful career in Egypt in 1898, when he was appointed a surgeon at the great Cairo hospital of Kasr-el-Ainy, and surgical teacher in the Ministry of Public Instruction, as the Ministry of Education was then called. As medical officer of the Anglo-American Hospital and the Victoria Deaconess Hospital, he not only did most of the surgical work required for the members of the British community, but also had a large practice among the Egyptian population of Cairo, and indeed of the whole of Egypt. Among his appointments were those of medical adviser to the High Commissioner for Egypt and to the British Consulate. But it was not so much in his large official and private practice that he did his most lasting work as in his labours at the Kasr-el-Ainy Hospital. To this institution, which now has 1000 beds, he devoted his chief energies, and as Professor of Surgery in the School of Medicine over many years he had as his pupils almost all the successful Egyptian surgeons of the present day. An immense amount of clinical material helped him to make valuable contributions to the surgery of bilharziasis, and he published a book on the "Surgery of Egypt" besides chapters in various systems of surgery and papers of surgical interest in the professional journals. During the war he was a civil surgeon attached to the Egyptian Expeditionary Force from 1915 to 1918, and was in charge of the surgical division in two military hospitals and at Kasr-el-Ainy. When a few years ago he retired from surgical and general practice it was to give himself with closer application to medical education and administration. How strenuously he was occupied may be gauged from the fact that at the time of his death he was not only Dean of the Faculty of Medicine and Director of the Kasr-el-Ainy Hospital, but was also acting Rector of the State University. For the past few years he had handled nearly all the details of the vast reorganisation of the Faculty, hospital, and school. A man of great ambitions, he could not rest until he had seen the fruition of his plans, which were to make the medical school at Cairo the equal of any in the world. He worked with such perseverance and unfailing good humour that difficulties which appeared insurmountable seemed to melt away and the proposed new hospital and medical school on Rhoda Island began to take concrete form. It was a happy coincidence that his scheme of development should have reached completion on the occasion of the international conference which took place last

December at the centenary celebrations of the school. It was on his shoulders that the chief burden of the Congress fell. How heavy this burden was is clear from the account of the proceedings published in THE LANCET of Jan. 12th, and from the supplementary note by Dr. Madden himself in our issue of Feb. 16th, and there can be no doubt that much of the success was due to his authority and leadership. In recognition of his work in this connexion he was created C.M.G. in the New Year's Honours, having previously received the O.B.E., and several Egyptian decorations.

Madden's abounding energy made it possible for him to get through a great deal more work than most men. Conscientious to a fault, his industry and devotion to duty were an example to all who came in contact with him. Among his colleagues and students he was deservedly popular, for he was sympathetic, unselfish, and ready to help in work or in overcoming difficulties. In addition to his official duties he took an active part in the public life of Cairo. An excellent tennis player, he was frequently to be seen at the Gezira Club, at which place and also in the Turf Club his genius for friendship made him a much sought-after companion, for his quiet kindliness and good nature won him general esteem. He had the confidence of his colleagues, Egyptian and European alike, and the respect in which he was held by the medical profession of Egypt is evident from the note in the *Times* of April 27th by the Egyptian Minister of Foreign Affairs, Dr. Hafez Afifi, one of his old pupils, who is now visiting this country.

Dr. Madden married in 1900 Madeline, daughter of the late Dr. William Cox of Winchcombe, Gloucestershire, who survives him with two daughters and two sons, one of whom is studying medicine in London.

Medical News.

UNIVERSITY OF CAMBRIDGE.—At a congregation held on April 26th the following degrees were conferred:—

M.D.—*W. S. Hunt, *A. C. Hampson, William Brockbank, and William Smith.

* By proxy.

M.B. and B.Chir.—J. D. R. Murray, J. G. Milner, and T. D. Morgan.

M.B.—C. A. Francis, Edward Clayton-Jones, and E. A. E. Palmer.

B.Chir.—E. B. Murrell.

UNIVERSITY OF LONDON.—At recent examinations the following candidates were successful:—

DIPLOMA IN PSYCHOLOGICAL MEDICINE.

With Special Knowledge of Psychiatry.—Joseph Braithwaite and Catherine M. Hext.

ROYAL COLLEGE OF PHYSICIANS OF LONDON.—An ordinary Comitia of the College was held on April 25th with Sir John Rose Bradford, the President, in the chair. The following Members of the College were elected to the Fellowship:—

Richard Walter Marsden, Rupert Waterhouse, Arthur Gurney Yates, Kenneth Douglas Wilkinson, Thomas Lionel Hardy, Geoffrey Bourne, Constantine Trent Champion de Crespigny, Archibald Cathcart Roxburgh, Basil Thomas Parsons-Smith, Arthur William Mickle Ellis, Harold Gardiner-Hill, Joseph Harold Sheldon, John Maurice Hardman Campbell, James Henry Dible, Donald Hugh Paterson, John Crighton Bramwell, Alfred Frank Tredgold, Hugh Gainsborough, Charles Hallilley Kellaway, Arthur Henry Douthwaite, Donald Hunter, and Hubert Maitland Turnbull.

Nominated by the Council under By-law XXXVIII. (*b*):

Charles Arthur Lovatt Evans, F.R.S.

The following candidates were elected Members of the College:—

Robert Stevenson Aitken, John Anderson, Ronald Winston Brookfield, Walter Eric Chiesman, Hugh Anthony Clegg, Gladys Mary Evans, Fergus Robert Ferguson, Walter Edward Fisher, Hugh Gregory Garland, Hector Kenneth Goadby, Cyril Arthur Keele, Alexander Joseph May, Manek Meherwanji Mehta, Louis Minski, Alan Gordon Ogilvie, William Esmond Rees, Hoe Min Sein, Eric Walter Skipper, William Raymond Courtenay Stowe, Moses Myer Suzman, Pendrill Charles Varrier-Jones, William Swanson Whimster, and Cyril Erskine Woodrow.

On the nomination of the President, Dr. F. E. Fremantle, M.P., was appointed to represent the College on the British Social Hygiene Council and to act as delegate to the Fourth Imperial Social Hygiene Congress to be held in London from July 8th to 12th.

A communication was received from the University of London intimating that the new Senate would be constituted towards the end of May or the beginning of June. The President explained that in accordance with the new constitution the College would no longer be represented on that body.

A communication was received from the Ministry of Health asking the College to proceed with the revision of the "Nomenclature of Diseases." On the nomination of the President, Dr. W. C. Bosanquet was elected secretary of the Revision Committee, the personnel of which will be elected at the next Comitia.

It was reported that with the concurrence of the President of the College the Medical Department of the Admiralty have awarded the Gilbert Blane Gold Medal for 1929 to Surgeon-Lieut. Commander Thomas Norman D'Arcy.

At the request of the Home Office the College has submitted a panel of names of persons suitable to fill the vacancy caused by the resignation of Sir Seymour Sharkey from the Advisory Committee on the Administration of the Cruelty to Animals Act.

Dr. O. K. Williamson was appointed a delegate to the Centenary Celebration of the South African College to be held at Cape Town from Oct. 1st to 5th.

Lord Dawson of Penn and Dr. A. P. Beddard were elected to serve, together with the President, on the Mackenzie Mackinnon Research Fund Committee (see p. 933).

Licences to practise were conferred upon 108 candidates who have passed the Final Examination in Medicine, Surgery and Midwifery of the Conjoint Board and have complied with the by-laws of the College. The following are the names and medical schools of the successful candidates:—

E. G. Abdel-Malek, Birmingham; D. A'Brook, Univ. Coll.; Annie D. M. Adams, Oxford and King's Coll.; C. L. Ahluwalia, Punjab and Charing Cross; Annie F. Allport, Royal Free; C. Arthur, Cambridge and St. George's; J. C. Arthur, Durham; S. Alstead, Liverpool; A. R. Banham, Cambridge and Middlesex; I. T. Barling, Cambridge and St. Thomas's; J. R. J. Beddard, St. Bart.'s; D. Bielenky, Westminster; H. E. Blake, Cambridge and St. Thomas's; M. Bloom, Cardiff; R. K. Bowes, Liverpool; A. M. Boyd, St. Bart.'s; J. S. B. Bray, Cambridge and St. Bart.'s; A. D. D. Broughton, Cambridge and London; C. W. F. Burnett, Univ. Coll.; E. L. Butler, Birmingham; C. E. Caudwell, Westminster; M. A. Chamberlain, Manchester; P. P. Chandu Nambiar, Bombay and Birmingham; Rosa O. J. Clark, Royal Free; J. O. Clyde, Middlesex; J. R. Colville, St. Bart.'s; S. J. Cope, St. Thomas's; D. M. Craig, Middlesex; F. A. D'Abreu, Birmingham; A. M. D'Cotta, Singapore and St. Mary's; J. G. Dathan, St. Thomas's; H. R. J. Donald, Oxford and Manchester; E. S. Fossey, Otago; I. Friedman, Guy's; Dorothea L. Gee, Royal Free; T. Giblin, Melbourne and St. Bart.'s; A. Gilpin, King's Coll.; Joan Goodger, Charing Cross; H. Gordon, Durham and Middlesex; E. Grundy, Leeds; P. N. Hanson and K. W. D. Hartley, St. Bart.'s; Dorothy C. Hay, King's Coll.; G. Herbert, Cambridge and St. Thomas's; J. H. Howells, Cardiff and Middlesex; D. Hugo, Cape and Guy's; A. H. Hussein, Cairo and Edinburgh; A. E. Hutton, Westminster; K. L. James, Univ. Coll.; W. H. P. Jonas, Oxford and St. Thomas's; C. Jones, Leeds; Mary E. H. Jones, Cardiff and Charing Cross; R. A. Jones, Cardiff and Univ. Coll.; L. D. Khatri, Bombay; H. V. Knight, Cambridge and St. Bart.'s; R. G. Krishman, Bombay and Birmingham; R. J. Krogh, Bristol; A. J. C. Latchmore, Leeds; J. C. Lee, Cambridge and London; J. M. Leggate, Liverpool; F. G. Lewis, Birmingham; O. V. Lloyd-Davies, Middlesex; J. V. Lucas, Cambridge and King's Coll.; H. G. McGregor, Guy's; C. G. Millman, King's Coll.; A. J. Moffett, Birmingham; B. A. Moss, Guy's; L. P. Naz and W. L. Neustatter, Univ. Coll.; J. C. Nicholson, Oxford and St. Bart.'s; R. J. L. O'Donoghue, Guy's; J. R. Owen, Birmingham; E. R. G. Passe, Melbourne and London; A. S. Philips and R. K. Price, St. Bart.'s; K. H. Pridie, Bristol; A. B. Rao, Madras and Middlesex; J. B. A. Reynolds, Cambridge and St. Bart.'s; R. A. C. Rice, St. Bart.'s; N. W. Roberts, Liverpool; C. St. Johnston, Birmingham; J. G. Sandrey, Sydney; R. W. Scanlon, Madras and St. Thomas's; C. P. Scott, St. Thomas's; J. D. W. Shedden, Birmingham; M. D. Shephard, Univ. Coll.; B. Singer, London; W. F. Skaife, Oxford and St. Bart.'s; D. B. Smallshaw, Guy's; W. C. Smallwood, Birmingham; E. S. Stern, Cambridge and Univ. Coll.; J. B. Sugden, Leeds; L. Sumitra, St. Mary's; N. C. Tanner, Bristol; L. Taylor, Sheffield; K. S. Thom, Birmingham; R. S. Thomas and A. E. Treweek, Guy's; J. J. van Niekerk, Cape and Guy's; E. Vitenson, Leipzig and Guy's; W. J. Walter, Oxford and St. Bart's; G. J. S. West, Bristol; S. J. Wheeler, Guy's; B. Williams, Edinburgh; D. C. Williams, Cardiff; E. R. Williams, St. Mary's; Sybil O. Williams, Calcutta and Royal Free; and Kathleen Wilson, Cambridge and King's Coll.

A supplementary list of licentiates is being issued later for candidates whose examinations were not completed when the above list was compiled.

Society of Apothecaries of London.—At recent examinations the following candidates were successful:—

Surgery.—B. L. Fishout, Cardiff: E. T. Garthwaite, St. Bart.'s Hosp.; E. Marks, St. Mary's Hosp.; A. N. De Monte, St. Thomas's Hosp.; C. J. Poh, Edinburgh; and P. U. Rao, Charing Cross Hosp.

Medicine.—B. L. Fishout, Cardiff; D. F. Michael, St. Mary's Hosp.; C. J. Poh, Edinburgh; and H. Whitby, London and St. Mary's Hosps.

Forensic Medicine.—H. M. Feldman, Leeds; H. Murkus, Birmingham; and A. W. Tam, Singapore and Edinburgh.

Midwifery.—L. Banszky, Middlesex Hosp.; G. R. Davies, St. Mary's Hosp.; C. W. Ellison, St. Bart.'s Hosp.; B. C. Ghose, Durham; C. F. H. Quick, St. Mary's Hosp.; and T. Singh, Charing Cross Hosp.

The Diploma of the Society, entitling them to practise medicine, surgery, and midwifery, was granted to H. M. Feldman and D. F. Michael.

Aberdeen University Club, London.—The eighty-first half-yearly dinner of this club will be held at the Trocadero Restaurant, Piccadilly-circus, on Thursday, May 16th. The hon. secretary's address is 9, Addison-gardens, W. 14.

International Society for Microbiology.—The first congress of this Society, which was to take place in Paris in October, 1929, has been definitely postponed until June 25th, 1930. The programme, which has already been published in various scientific journals, will stand.

Among those called to the Bar on April 24th were Dr. W. E. Masters (Middle Temple) and Dr. L. P. Lockhart (Gray's Inn).

The foundation-stone of the Eastman Dental Clinic, attached to the Royal Free Hospital, was laid on Tuesday last by the Prince of Wales. His Royal Highness was received by Lord Riddell, the Chairman of the Hospital, and the Prime Minister and the Minister of Health were present. The Prince of Wales emphasised the significance of a gift of such generous character from an American citizen to a great London Hospital, and the Prime Minister dwelt on the value to a nation of good teeth.

Presentation to a Medical Man.—Dr. Charles Firth, formerly of Gravesend, on the occasion of his retirement from practice and his removal from the county, was recently the recipient of a presentation from members of the Kent Local Medical and Panel Committees in the form of a silver salver as a token of the high esteem in which he was held by his colleagues and a mark of the appreciation of the very valuable assistance given to the committees over a long term of years. Owing to his illness the presentation was carried out at Dr. Firth's residence in Twickenham by a deputation of the members of the committee. Dr. Firth was for a number of years chairman or vice-chairman of the committees and was also a member of the Insurance Committee for the county of Kent and its Medical Service Subcommittee.

Factory Chimneys and Rainfall.—At the annual meeting of the Manchester Literary and Philosophical Society on April 23rd Dr. Ashworth, who has been investigating the relation of rainfall to smoke pollution in Rochdale, suggested that smoke from mill chimneys has an appreciable influence on rainfall. He has found that over a period of ten years in Rochdale Sundays were the driest day of the week and had an average rainfall 13 per cent. lower than the average per day of the whole week. In Rochdale also more rain fell during the day period of week-days—when the mills were working—than at night: whereas the reverse was true of Sundays. A close relation was found between the rate at which rain falls (in inches per hour) and the fluctuations in the emission of smoke.

Nitrogenous Fertilisers from the Air.—Addressing the British Science Guild at the Mansion House, London, on April 24th, Sir Frederick Keeble, F.R.S., said that in this country and abroad nitrogen of the air was now being made into fertilisers at the rate of over 1 million tons per year. In 1913, farmers throughout the world used annually about 750,000 tons of nitrogen in its various forms; in 1928 the total agricultural consumption amounted to nearly 1½ million tons. Different nations were acquiring the nitrogen habit at different rates. Holland led the way, followed by Belgium and Germany, with Japan fourth, Egypt fifth, and Great Britain sixth. France lagged behind England and the United States was well below Western European countries. The present price of fertiliser was low; indeed it might be called the only cheap thing in the world to-day. The application of 1 cwt. of nitrogenous fertiliser to the acre gave an increase of 2½ cwt. per acre of cereals and 1 ton of "roots" in the case of potatoes or swedes; and so on for other crops. Already 6000 workers were employed at the factory at Billingham, which had an output of 50,000 tons in 1924, and was expected to reach an output of 750,000 tons by 1930.

We regret to announce that Dr. William McConnel Wanklyn, consultant in the diagnosis of small-pox to the London, Middlesex, and Essex County Councils, died on Tuesday in his office at the County Hall, Westminster. A paper by him appeared in our last issue.

The Royal Victoria Infirmary, Newcastle-on-Tyne, has received a cheque for £2000 from an anonymous donor for the purchase of radium for the treatment of cancer.

St. George's Hospital.—It is stated that this hospital will shortly receive an unexpected legacy of between £15,000 and £20,000, which will go towards reducing the overdraft of about £40,000.

We are informed that the honorary assistant surgeons of the Golden-square Throat, Nose and Ear Hospital, London, will in future be allotted their own sessions for operating upon in-patients.

St. Cross Hospital, Rugby.—On Saturday last the Duchess of York opened the new "Arthur James" out-patient department and casualty wards, given by Mrs. Arthur James, Her Royal Highness's godmother, in memory of her husband. More than one-third of the population of Rugby contributes regularly to the hospital.

Colony for Mental Defectives.—It is stated that great difficulty is found in providing accommodation for mental defectives in the county of Cheshire. The Cheshire County Council, in coöperation with the city of Chester and the county boroughs of Wallasey and Birkenhead, has been dealing with the problem of accommodation for these mental cases, and a large estate near Holmes Chapel has been purchased for use as a colony for the mentally deficient.

Kensington General Hospital.—The Marquis of Carisbrooke presided last week at a Mansion House dinner on behalf of the fund for rebuilding the Kensington, Fulham, and Chelsea General Hospital. It was explained that although only £20,000 of the necessary £100,000 had yet been raised, most of which had been expended on the purchase of the site, it had been found impossible to delay the rebuilding, and the work is now proceeding, most of the old structure having been demolished.

Rating of Hospitals.—Middlesex County Council last week agreed that hospitals and similar institutions supported wholly or partly by voluntary contributions should be exempt from rating. The County Valuation Committee were asked not to offer any opposition in the event of proposals being made with that object. Alderman G. Marlow Reed, vice-chairman of the Council, stated that "by exempting its hospitals and charitable institutions from rates Middlesex has led the way and set an example which other county councils are certain to follow."

Medical Diary.

Information to be included in this column should reach us in proper form on Tuesday, and cannot appear if it reaches us later than the first post on Wednesday morning.

SOCIETIES.

ROYAL SOCIETY OF MEDICINE, 1, Wimpole-street, W.

Tuesday, May 7th.—5.30 P.M., Orthopædics (Cases at 4.30 P.M.). Annual General Meeting: Election of Officers and Council. Clinical Cases: Mr. Laming Evans: A Case of Kienbock's Disease of the Semilunar bone. Mr. C. Lambrinudi: A Case with Primary Torsion of the Tibiæ. Other cases will be shown.

Wednesday.—4.45 P.M., Surgery: Sub-Section of Proctology. Annual General Meeting: Election of Officers and Council. Discussion (at 5 P.M.) on Fistula-in-ano. Opener: Mr. J. P. Lockhart-Mummery. Followed by (1) Mr. H. A. Harris, on the Hind-end of the Embryo in Relation to Fistula-in-ano, (2) Mr. C. Naunton Morgan on the statistical side. The Annual Dinner will take place at the Trocadero Restaurant, Piccadilly-circus, W. 1, on the same evening, at 8 P.M. for 8.30 P.M.

Thursday.—8.30 P.M., Neurology. Annual General Meeting: Election of Officers and Council.

Friday.—5.30 P.M., Clinical: (Cases at 5 P.M.) Annual General Meeting: Election of Officers and Council. Cases: Dr. Sibyl Eastwood: 1. Meningioma after Operation. 2. Diverticulum of the Stomach. Dr. O. Leyton: 3. Persistent Hypoglycæmia following Diabetes Mellitus. Mr. Cecil P. G. Wakeley: 4. Acute Osteomyelitis of the Tibia after Bone Grafting. Dr. Norman Hill: Multiple Deformities. Other cases will be shown.

Saturday and Sunday.—Balneology and Climatology: Annual Provincial Meeting at Harrogate.

ROYAL SOCIETY OF ARTS (Indian Section), John-street, Adelphi, London, W.C.

Friday, May 10th.—4.30 P.M., Mr. P. Johnston-Saint, F.R.S. Edin.: An Outline of the History of Medicine in India. (Sir George Birdwood Memorial Lecture.)

WEST KENT MEDICO-CHIRURGICAL SOCIETY, Miller General Hospital, Greenwich, S.E.

Friday, May 10th.—8.15 P.M., Mr. C. A. Joll: Radium: Its Place in the Treatment of Malignant Disease. Presidential address.

LECTURES, ADDRESSES, DEMONSTRATIONS, &c.

FELLOWSHIP OF MEDICINE AND POST-GRADUATE MEDICAL ASSOCIATION, 1, Wimpole-street, W.

Monday, May 6th, to Saturday, May 11th.—Medical Society Lecture Room, 11, Chandos-street, Cavendish-square, W., M.R.C.P. Course of Instruction. Lectures on Tuesdays and Fridays at 8.30 P.M. Tues., 7th, Dr. B. T. Parsons-Smith: The Assessment of Valvular Heart Disease. Frid., 10th. Dr. B. T. Parsons-Smith: The Treatment of Cardiac Failure.—King's College Hospital, Denmark Hill, S.E. Demonstration in the Children's O.P. Department by Dr. Wilfrid Sheldon on Wed., at 2.30 P.M. No fee.—Cancer Hospital, Fulham-road, S.W. Demonstration by Mr. A. Lawrence Abel on Frid., at 2 P.M. No fee.—West End Hospital for Nervous Diseases, 73, Welbeck-street, W., Lecture-demonstration illustrated by cases. Daily at 5 P.M.—Maudsley Hospital, Denmark Hill, S.E., Course in Psychological Medicine. Every afternoon for four weeks.—Central London Ear, Nose and Throat Hospital, Gray's Inn-road, W.C., Intensive course of clinical instruction. All day course.—London Lock Hospital, Dean-street, W., *Afternoon course in* Venereal Disease for one month.—St. John's Hospital, Leicester-square, W.C., Course in Dermatology. Clinical instruction every afternoon.—Further particulars from the Fellowship of Medicine.

NATIONAL HOSPITAL, Queen-square, W.C.

Monday, May 6th.—12 noon, Dr. J. G. Greenfield: The Cerebro-spinal Fluid. 2 P.M., Dr. George Riddoch: Out-patient Clinic. 2.30 P.M., Dr. Adie: The Localisation of Cerebral Tumours.

Tuesday.—2 P.M., Dr. Walshe: Out-patient Clinic. 3.30 P.M., Dr. Critchley: Neurological Complications of Vertebral Diseases.

Thursday.—2 P.M., Dr. Kinnier Wilson: Out-patient Clinic. 3.30 P.M., Mr. Julian Taylor: Lesions of Peripheral Nerves.

Friday.—12 noon, Dr. Purdon Martin: Anatomy and Physiology of Nervous System. 2 P.M., Dr. Adie: Out-patient Clinic. 3.30 P.M., Mr. Elmquist: Demonstration of Re-educational Methods.

WEST LONDON HOSPITAL POST-GRADUATE COLLEGE, Hammersmith, W.

Monday, May 6th.—10 A.M., Dr. Dowling: Skin Department. 2 P.M., Mr. Donald Armour: Operations. 2 P.M., Dr. Ironside: Medical Out-patients.

Tuesday.—10 A.M., Medical Registrar: Ward Visit. 2 P.M., Mr. Addison: Operations. 2 P.M., Mr. Sinclair: Surgical Out-patients.

Wednesday.—10 A.M., Dr. Owen: Children's Out-patient Department. 2 P.M., Mr. Tyrrell Gray: Operations. 2 P.M., Dr. Scott Pinchin: Medical Out-patients.

Thursday.—10 A.M., Dr. Grainger Stewart: Neurological Department. 11.30 A.M., Mr. Simmonds: Demonstration of Fractures. 2 P.M., Mr. MacDonald: Genito-Urinary Out-patient Department.

Friday.—10 A.M., Dr. Pritchard: Medical Ward Visit. 12 noon, Dr. Shaw: Clinical Demonstration. 2 P.M., Mr. Vlasto: Throat, Nose and Ear Department.

Saturday.—9.30 A.M., Dr. Burnford: Bacterial Therapy Department. 10 A.M., Dr. Owen: Children's Medical Out-patient Department. 10 A.M., Resident Assistant Surgeon: Ward Visit. Medical and Surgical Out-patients at 2 P.M., daily. Operations. Special Departments daily, 10 A.M. to 5 P.M., Saturdays 10 A.M. to 1 P.M. Special Classes in Anæsthetics and Operative Surgery.

NORTH-EAST LONDON POST-GRADUATE COLLEGE, Prince of Wales's General Hospital, Tottenham, N.

Monday, May 6th.—2.30 to 5 P.M.: Medical, Surgical, and Gynæcological Clinics. Operations.

Tuesday.—2.30 to 5 P.M.: Medical, Surgical, Throat, Nose and Ear Clinics. Operations.

Wednesday.—2.30 to 5 P.M.: Medical, Skin, and Eye Clinics. Operations.

Thursday.—11.30 A.M.: Dental Clinics. 2.30 to 5 P.M.: Medical, Surgical, Nose, Throat and Ear Clinics. Operations.

Friday.—10.30 A.M.: Throat, Nose and Ear Clinics. 2.30 to 5 P.M., Surgical, Medical, and Children's Diseases Clinics. Operations.

EAST LONDON HOSPITAL FOR CHILDREN, Shadwell, E.

Wednesday, May 8th.—4.15 P.M., Clinical Meeting and Discussion on the Significance of Otitis Media in Influenza, to be followed by demonstration of cases of interest. All practitioners are cordially invited. Tea at 4 P.M.

UNIVERSITY COLLEGE, Gower-street, London.

Thursday, May 9th.—5 P.M., Mr. R. J. Lythgoe: Special Sense Physiology. (Second of six lectures.)

Friday.—4 P.M., Prof. A. J. Hall: Some of the Sequels of Epidemic Encephalitis (Lethargica). (Last of two public lectures.)

ST. THOMAS'S HOSPITAL, Albert Embankment, Westminster Bridge, S.E.

Thursday, May 9th.—5 P.M., Prof. S. J. Cowell: Dietetics. (Second of six lectures.)

ROYAL NORTHERN HOSPITAL, Holloway-road, N.

Wednesday, May 8th.—3.15 P.M. (at the Royal Chest Hospital, City-road), Dr. W. Barty King: Cases Illustrating some Difficulties in the Diagnosis of Diseases of the Chest.

LONDON SCHOOL OF DERMATOLOGY, St. John's Hospital, 49, Leicester-square, W.C.

Monday, May 6th.—5 P.M., Dr. H. Haldin-Davis: Drug Eruptions.

Tuesday.—Dr. H. W. Barber: Alopecia Areata and Vitiligo.

Thursday.—Dr. S. E. Dore: Animal Parasites.

Friday.—Dr. G. B. Dowling: Skin Diseases due to Protein Sensitisation.

ROYAL DENTAL HOSPITAL POST-GRADUATE *LECTURES.*

Wednesday, May 8th.—6 P.M., Mr. J. G. Turner: Pain.

MANCHESTER ROYAL INFIRMARY POST-GRADUATE COURSE.

Tuesday, May 7th.—4.15 P.M., Dr. J. C. Bramwell: Cardiac Œdema and its Treatment.

Friday.—4.15 P.M., Mr. D. L. Sewell: Demonstration of Otological and Laryngological Cases.

Appointments.

Coope, Robert, M.D. Liverp., M.R.C.P. Lond., has been appointed Hon. Assistant Physician, Liverpool Royal Infirmary.

Coope, H. M., M.B., Ch.B. Manch., to be Certifying Surgeon under the Factory and Workshop Acts for Lytham.

Vacancies.

For further information refer to the advertisement columns.

Aberdeen, Royal Hospital for Sick Children.—Hon. Asst. S.

Ashton-under-Lyne, District Infirmary.—H.S. At rate of £150.

Bath, Royal United Hospital.—H.P At rate of £120.

Bedford County Hospital.—Asst. H.S. At rate of £130.

Birmingham and Midland Eye Hospital, Church-street.—Surgical Registrar.

Blackburn and East Lancashire Royal Infirmary.—Fourth H.S. At rate of £130.

Bolingbroke Hospital, Wandsworth Common, S.W.—Clin. Asst. to Ear, Nose and Throat Dept. £75.

Brighton, Royal Sussex County Hospital.—Cas. H.S. £120.

Bristol University.—Chair of Physiology.

Burnley, Victoria Hospital.—H.S. At rate of £125.

Bury St. Edmund's, West Suffolk General Hospital.—H.S. £150.

Cambridge, Papworth Village Settlement.—H.P. £100–£200 per annum.

Croydon County Borough.—Asst. M.O.H. and Asst. School M.O. £600.

Derby Guardians Institution and Infirmary.—Second Res. M.O. £250.

East London Hospital for Children, &c., Shadwell, E.—Res. H.S. Also Res. Cas. O. Each at rate of £125.

Folkestone, Borough of.—Asst. M.O.H. £600.

Golden-square, Throat, Nose and Ear Hospital, W.—Clinical Assistant.

Gordon Hospital for Rectal Diseases, Vauxhall Bridge-road, S.W. H.S. £75. Also Hon. Asst. Surgeon.

Gravesend and North Kent Hospital.—Jun. H.S. At rate of £80.

Hackney Hospital, High-street, Homerton, E.—Jun. Asst. M.O. £350.

Hospital of St. John and St. Elizabeth, 60 Grove End-road, N.W.—Res. H.P. At rate of £100.

Hull Royal Infirmary.—Cas. H.S. At rate of £130.

Ilford Borough Council.—Asst. School Dental Surgeon. £450.

Lambeth Parish Hospital, S.E.—Jun. Asst. M.O. £200.

Leamington Spa, Warneford General Hospital.—Res. H.P. Also Res. H.S. Each £165.

Leeds Public Dispensary.—Jun. Res. M.O. £150.

Leicester Royal Infirmary.—Third Res. Anæsthetist. At rate of £250.

Lenham Sanatorium.—Asst. M.O. £400.

Liverpool Eye and Ear Infirmary, Myrtle-street.—H.S. to Ear, Nose and Throat Dept. £100.

London Hospital, Whitechapel, E.—Jun. Gynæcological First Asst. £300.

Manchester Royal Infirmary.—Hon. Asst. Physician to Out-Patients.

Manchester University.—Dr. Robert Angus Smith Scholarship. £150.

Manchester, Victoria Memorial Jewish Hospital, Cheetham.—Hon. Aural Surgeon. Also Sen. H.S. £250.

Margate Royal Sea-Bathing Hospital.—H.S. At rate of £100.

M.A.B. Mental Hospitals Service.—Sen. Asst. M.O. £650.

Mexborough, Yorks, Montagu Hospital.—Jun. H.S. £100.

Middlesex County Council.—Asst. M.O. £600.

Miller General Hospital, Greenwich-road, S.E.—Out-Patient Officer. At rate of £150.

Newcastle-upon-Tyne, University of Durham College of Medicine.—Whole-time Assistant. £400.

Nottingham Children's Hospital.—Res. H.S. At rate of £130.

Nottingham General Hospital.—Res. Cas. O. At rate of £200

Romford, Oldchurch Hospital.—Third Res. Asst. M.O. £250.
Royal Free Hospital, Gray's Inn-road, W.C.—Asst. Morbid Anatomist and Curator of Museum. £300.
Royal National Orthopædic Hospital, 234, Great Portland-street, W. Surgical Registrar. At rate of £105.
Royal Northern Hospital, Holloway, N.—H.S. At rate of £70.
Samaritan Free Hospital for Women, Marylebone-road, N.W.—Anæsthetist. £30.
St. Bartholomew's Hospital, E.C.—Asst. Physician.
St. Peter's Hospital for Stone, Henrietta-street, Covent Garden, W.C. Clinical Pathologist. £250.
Sheffield, Winter-street Hospital.—Asst. Tuber. O. £450.
Singapore Municipality of Straits Settlements.—Health Dept. Asst. Municipal Health Officer. £980.
Southampton County Borough.—Asst. M.O.H. £600. Also Asst. School Dentist. £450.
Taunton and Somerset Hospital.—Jun. House M.O. At rate of £100.
University of London.—University Chair of Anatomy. £1000.
Walsall General Hospital.—Jun. H.S. At rate of £100. Also H.S. At rate of £125.
Whipps Cross Hospital, Whipps Cross-road, Leytonstone, E.—Res. Asst. M.O.'s. Each £300.
Will Edmonds Clinical Research Fund.—Fellowship. £500.
Winchester, Royal Hampshire County Hospital—H.P. At rate of £150. Also Hon. S. in Ordinary.
Wolverhampton, Royal Hospital.—Cas. O. and Res. Anæsthetist. At rate of £125.
Wolverhampton and Midland Counties Eye Infirmary.—H.S. £200.

Births, Marriages, and Deaths.

BIRTHS.

Dickson.—On April 26th, the wife of W. Muir Dickson, F.R.C.S., *of a son.*

Fletcher.—On April 28th, at Harley-street, W., the wife of Herbert Morley Fletcher, M.D., F.R.C.P., *of a daughter.*

Harkness.—On April 25th, at Welbeck-street, W., the wife of Robert Coltart Harkness, F.R.C.S., Bermondsey Hospital, S.E., of a daughter.

Holden.—On April 23rd, at Byron House, Aylesbury, the wife of Dr. S. J. C. Holden, of a daughter.

Moor.—On April 27th, at Granville Lodge, Westgate-on-Sea, the wife of Dr. Frewen Moor, *of a son.*

Salisbury.—On April 29th, at Woodlands, 28, Billing-road, Northampton, to Constance, wife of Walter Salisbury, M.D., *M.S., F.R.C.S.*—a daughter.

Wilson.—On April 24th, the wife of Archibald Wilson, O.B.E., M.C., M.B., Ch.B., Moselle House, High-road, Tottenham, N., of a son.

DEATHS.

Bailey.—On April 25th, at Geneva, William Henry Bailey, M.D., Barrister-at-Law, late of Featherstone Hall, Southall, Middlesex.

Dawes.—On April 18th, 1929, very suddenly, Joseph William Dawes, M.B., C.M. Edin., of Denbigh House, Longton, Staffordshire, aged 65 years.

Frost.—On April 22nd, at Primrose Hill, Langton Matravers, George Frost, M.D., aged 75.

Henderson.—On April 29th, at the Sanatorium, Mundesley, George Thompson Henderson, B.A., B.Chir. Camb., M.R.C.S., L.R.C.P.

Lee.—On April 27th, died instantly in an accident, Edward Sidney Thomas Lee, elder son of Dr. and Mrs. W. E. Lee, *of 17,* Princes-avenue, Muswell Hill.

Rabagliati.—On April 28th, at Leeds, Andrea Francis Honyman Rabagliati, M.D., F.R.C.S.E., late of Durban and Nairobi, aged 50.

Smith.—On Feb. 25th, 1929, at the American Mission Hospital, Ranipet, South India, of acute intestinal obstruction, James Ironside Smith, Indian Civil Service, District and Sessions Judge of Chittoor, the dear husband of Amy M. Thoms, M.D., M.R.C.P.

Wilde.—On *April 23rd,* at his residence, 23, The Circus, Bath, Percy Roberts Wilde, M.D. Aberd., M.B., C.M., Hon. Physician Lansdown Hospital and Nursing Home, Bath, in his 72nd year.

N.B.—A fee of 7s. 6d. is charged for the insertion of Notices of Births, Marriages, and Deaths.

Donations and Bequests.—*Mr. John Barrow* Hope, of Wyngates, Bournemouth, left, after the death of his wife, £1000 each to the Children's Convalescent Home, West Kirby, the Lear Home of Recovery, West Kirby, Manchester Royal Infirmary, Ancoats Hospital, Manchester, St. Mary's Lying-in Hospital, Manchester, and the Imperial Cancer Research Fund.—Mr. Alfred Hobson, of Redcliffe, Dawlish, who left estate of the value of £110,000, after various gifts including £3000 to the Cancer Hospital, Fulham-road, S.W., and £500 each to the West of England Eye Infirmary and the Zenana Mission, left the residue of the estate—i.e., the bulk of the property—to such charitable objects as his executors shall determine.—Mrs. Florence Churchill Hale, of Hyde Park-place, W., left £500 each to the London Hospital, the Dental Hospital, Leicester-square, and the British Home for Incurables, Streatham, less sums given after the date of her codicil.

Notes, Comments, and Abstracts.

SOME FACTORS WHICH HAVE MADE FOR THE DECLINE OF NATIONS.*

By Sir Thomas Oliver, M.D., F.R.C.P.,

VICE-CHANCELLOR OF THE UNIVERSITY OF DURHAM.

Just as many factors contribute to the uplifting of a race, so also do many factors operate in causing its decline. When we come to consider the pathological causes which lead to a racial decline, we find that it is less through severe forms of epidemic disease sweeping over a country and decimating it than of widespread endemic disease which, lingering in a country, causes a high death-rate of its young people, undermines the health of its adults so that they fail to reproduce physically strong descendants. The civilisation of Greece is one of the outstanding facts of history. In the fourth century B.C. a change had taken place in the Greek character. It was not due to increased immorality, though morality had altered behaviour. Men and women still preferred home to city life: patriotism had, however, declined, and the people had lost their manly vigour and intellectual strength. To what extent decay of religion contributed to this end it is difficult to say. It was at this period that malaria is known to have been prevalent in Greece, but, unlike such epidemic diseases as small-pox and plague, malaria tends to become chronic; it does not weed out a race all at once, but it creates general debility and undermines virility. The geographical conditions of Greece with her mountain valleys lent themselves to the development and spread of malaria, for to-day, even after several years of hygienic efforts, 40 per cent. of the people are said to be suffering from the malady. The disease was known to Hippocrates, while Galen in the second century A.D. accurately describes the seizures with their quotidian and tertian peculiarities. It is not known at what date malaria was introduced into Greece or where it came from, but as it is an African disease it was probably introduced by ships trading with Egypt, or it may have come by way of Asia. Herodotus, writing of the people of Egypt who were living in the marshes, states that they were plagued with gnats and at night they wrapped themselves in a net in bed. This was the dawn of the mosquito theory of malaria. One of the effects upon an agricultural people like those of Greece stricken by malaria would be that tracts of land would pass out of cultivation and that those lands thus left derelict would remain undrained and become more and more breeding-grounds of the mosquito. From the peninsula the infection was probably carried by Greek slaves or by *soldiers into* Italy.

Of the early effects of chronic malaria exhibited by the Greeks mention may be made of melancholy; the victims are said to have become neurotic and to have suffered from nervous depression. There has been considerable controversy over the decline of Greek morality which occurred in the fourth century B.C. It was not so much that type of immorality with which the word makes us familiar, as an alteration of the mental powers and temperamental condition of the Greeks, who, losing their nerve, began to take less interest in matters of State and ceased to be initiative. It is not maintained that malaria was the only factor which brought about this change of character in the Greeks, and led to their decline. The Greek had not only lost his religion but his faith, and without faith in something higher than itself no nation can long survive. Success in commerce and her highly developed merchant navy made Greece wealthy and supplied her with the means of gratifying luxurious tastes. Vice was not unknown and wars by their losses had drained the young life of the country. It was not when Greece was writhing under the grip of malaria that her people produced those works of art, literature, and philosophy which will for ever remain outstanding evidences of a height of civilisation no country has since attained.

Malaria in Ancient Italy.

With the exception of a few areas, Italy offers fewer breeding places for the mosquito than Greece. Although there is no definite information as to how malaria was introduced into Italy, it was probably carried thither from Africa by Hannibal's Carthaginian Mercenaries. It was prevalent in the country 50 years B.C., and was endemic in Rome and the Campagna. Here, as in Greece, the malarially affected districts passed out of cultivation. Prof. North, in his book on Roman fever, says that the effect of the disease upon the people was to unfit them for labour, to cause loss of time and money, to diminish their producing powers so that the race, if left to itself, would tend towards moral and physical degradation. Taken all round, malaria is perhaps one of the most incapacitating diseases to which man is liable and is the cause of the greatest amount of sickness. *Rome was a hotbed of malaria, so there was* every probability of her people becoming deteriorated. As a result of frequent wars, and of the country districts having become devastated, there was a rush of people to the large Italian towns and to Rome particularly. Thoughtful statesmen of the period recognised what was taking place and did all they could to get the people to return to the land, but all to no purpose, for economic conditions were unfavourable as well as the change in the national character consequent upon war. Thus overcrowded, the population of Rome gradually changed its outlook upon life.

---

* Abstract of a Presidential Address delivered at the Institute of Hygiene, London, on April 25th, 1929.

We have seen how malaria was a factor in enfeebling the Greek character and in causing the people to lose their initiative and purpose, but in the case of the Roman it appeared to produce entirely different effects. Mr. H. S. Jones reminds us of atrocities committed now and then by white men in the tropics, outbursts of savagery, attributable to malaria. I have no direct knowledge of such events having taken place, but it is stated that something of this kind happened in Rome. The pictures of life in the first century A.D. painted by Tacitus and Juvenal show Roman society to have been not only wicked but debased. The extravagant cruelty, the wild desire *for* excitement, and the absence of self-control, point to some psychical defect in the people. I am not prepared to say to what extent, if any, the change in Roman character was a consequence of malaria. Rome had lived her life of luxury and debauchery, and these of themselves were sufficient to change the national character.

Climate and Civilisation.

In the civilised world to-day those nations are certainly the most virile where the seasons vary and the temperature is moderate. Men are stimulated or depressed by climatic conditions. The varying capability of 500 factory operatives in the cities of New York, New Britain, and Connecticut, of 3000 factory operatives in the southern cities between Virginia and Florida, 1700 naval and military students at Annapolis and West Point *was tested by* Ellsworth Huntington in order to test the influence of climate on work. The districts, especially the two first mentioned, are separated by sufficient longitude as to have different types of weather. The experiments were carried on for a year, with the following results. Changes in the barometer had little effect; humidity possessed considerable influence, but temperature was clearly the most important element. All who took part in the experiment were most physically active when the temperature ranged between 60° and 70° F. Change of temperature was helpful, for the people did not work well when the temperature remained constant. The conclusion drawn was that a close agreement exists between the distribution of human energy and climatic and temperature findings—in other words, where civilisation is high a peculiar type of climate prevails. What *is* true to-day was *also* probably true of the past.

As regards climate, while it may contribute to natural progress it cannot be a cause of civilisation. But if it cannot be regarded as a cause, may an alteration of climate not become a contributory circumstance to its decline? Huntington's experiments are interesting as showing the optimum temperature under which work can best be carried on. Surveying the cultural achievements of eight civilisations Spengler, in his "Decline of the West," finds in every instance the same identical laws of birth, growth, maturity, and decline, the decline in every instance being preceded by the domination of intellect over race, or in other words by the influence of overgrown city populations, their arrogance and distaste of agricultural pursuits. To *Spengler, all civilisations* begin with a feudal condition and end in the life of great cities—they pass from the primitive arts to craft, into a period of criticism and greater intelligence, and finally into a stage when life itself, and not what use we make of it, becomes the all-engrossing problem.

Whither Civilisation is Tending.

To-day thoughtful men of the higher nations are asking what civilisation is doing for man, and *whither it is tending?* Modern civilisation is entirely different to any of the past. It is not confined to a small portion of the world's area. Setting aside China, it extends from the Far East through Asia and Europe to America.

Modern civilisation, in the form in which we know it to-day, dates from the introduction of machinery, or what is known as the Industrial Revolution, beginning in England in or about 1760. Machinery did not destroy, but it completely altered the thought and customs of Great Britain by revolutionising the life of the people, gradually transforming them from the serfdom of labour to more dignified types of work and with leisure to enjoy life.

Each age carries its own customs. We might well ask therefore whether the social and economic conditions of our time are altering national character? We are living perhaps too close to events to be able to appraise them at their proper value. The emancipation of woman remains one of *the* important events of our *time*. Young women earning income no longer feel that they are under any obligation to parents or to home, and therefore claim the right to act as they think best. Many of them use their freedom with great discretion and have shown the useful part they can play in social welfare. But we have been discussing not the question of sex nor of personal benefit, but whether modern civilisation will continue *and if possible* be improved. The declining acceptance of the responsibility of motherhood, the disinclination on the part of many women to marry, protracted postponement of the event, limitation of family and easy divorce are circumstances which cannot be ignored by students of racial biology. In our own country the number of unmarried women outstrips that of men. In the United States it is the reverse which prevails. In 1920 there were 9,611,902 unmarried women of 15 years and upwards; the number of unmarried men of the same age-period was 12,987,605, and yet while in the States there are more unmarried men than women there are the same circumstances—viz., few marriages, postponement of the event, and small families or none at all. How are these circumstances likely to influence for good the cause of civilisation?

The Lessons of Experience.

Ancient civilisations concerned themselves with hundreds of thousands of people, modern civilisation concerns itself with millions, all brought into close touch with each other by the abridgment of distance and the spanning of time. The conquest of nature has armed man with powers he never possessed until to-day, so that nations separated by thousands of miles from each other know what is taking place almost simultaneously. Modern civilisation has ceased to follow the customs and traditions of those of more ancient people. It refuses to be bound by the shackles of authority and claims the right of self-assertion. Mechanism and science are the powers which make for human progress. *These bring wealth to a country, also* higher wages, better food, and shorter hours to the workers. The cities tend to become overcrowded, and according to some writers, this is regarded as a prelude of national decline. In the growth, development, and decline of nations there is an analogy to the individual life, but there is a difference—the aged individual cannot recreate youth or revive within himself youthful methods of solving problems, but a nation composed of men and women of various ages can for legislative ends be grouped together, the decisions arrived at showing how the venturesome spirit of youth can be curbed by the experience of age and still the nation remain young.

Conquest, migration, disease, climate, and change of trade routes have all been advanced as causes of failure of the old civilisations. Wealth, luxury, and vice are often mentioned as the cause of the fall of the Roman Empire, while the fall of Babylonian civilisation was the result of wars and excessive taxation. Can our own or any country learn from the experience of past civilisations? It is with nations as with individuals—it is during the years of strenuous effort when men must work and life is frugally lived, that a people is becoming stronger and stronger and rising into power, and not when wealth has accumulated and *luxury prevails that a people is at its best. Are wealth,* luxury, and desire the aim and objects of civilisation? If so, then civilisation appears to develop and to sow the seeds of her own destruction.

ASYMMETRY IN THE ANIMAL BODY.

On April 24th Mr. C. J. Bond read a paper before the Eugenics Society on Hemilateral Asymmetry in Animals and Man, and its Relation to Cross-breeding.

From the genetic point of view, he said, discussion of this problem started from the well-known fact that the vertebrate organism, in common with that of some invertebrates, was built up on a bilateral plan. It might not be too fanciful to regard man, the *individual*, as composed of two *half* individuals joined together along the median plane. These two halves, as far as limbs, muscular structures, sense organs, and certain appendages like ears, horns in cattle, and other structures were concerned, were reduplications or mirror images of the same type. Sometimes bilateral symmetry broke down, and the study of asymmetric cases, both in man and animals, was of much importance.

The prehistoric races of oxen, and those of Eastern countries to-day were characterised, said Mr. Bond, by an upward curve of horn growth. On the other hand, in Western Europe a race of cattle seemed to have arisen with a downward curve. These differences were still seen in modern breeds, such as longhorns, Herefords, Lincolns, and Welsh cattle. Examples of asymmetry, in which a downward curve was present on one side and an upward curve on the other in the same individual, were especially frequent in cross-bred animals, as in modern shorthorn.

Again, the result of crossing a four-toed breed of bird —e.g., game—with a five-toed breed (Dorking or Chinese silky fowl) was the production in the first generation of birds, which mostly had five toes. Some of them, however, were *odd-toed or asymmetric, having five toes on one leg and four* on the other. Mr. Bond showed a photograph of a pheasant which was male on one side and female on the other, with a well-developed spur on the male side. He pointed out that the influence of the cross-breeding—i.e., the introduction of the factor or controlling influence for the extra digit in fowls—might extend in later generations to the other toes, and might bring about an irregular development of claws both in the toes and at the end of the wing bones.

Other examples were drawn from the result of the marriage of a person with large ears with well-developed "lobes," with another person with small ears and scanty ear lobes; the children showed both types of ear pattern, and in one individual an asymmetric pattern on the two sides of the head. The same thing was apt to happen with the colour of the eyes in man and animals.

The conclusion was reached that hemilateral asymmetry *was closely associated with previous cross-breeding*. The process by which the asymmetry of eye colour, or ear shape, or horn curve, was brought about was essentially one of segregation or differentiating cell division. This, in the case of Mendelian segregation, took place among the germ cells which, on fertilisation, gave rise to individuals having different genetic characters; whilst, in the case of asymmetry in the same individual, the cell differentiating process was concerned with the multiplication and growth of the body cells at that stage of embryonic development when the bilateral plan of growth was laid down in the growing embryo. Since eugenic progress along sound lines must rest on genetic knowledge, Mr. Bond hoped that the study of asymmetry or dissimilarity in the individual, like the study of dissimilarity among individuals, would lead to further progress along genetic lines.

HOME TREATMENT OF PANEL PATIENTS.

AT an inquest on a man of 40, who died from lobar pneumonia after a few days' illness, the Shoreditch coroner, Dr. Edwin Smith, made some comment on the treatment which he had received. According to the account in the daily press the patient, who was a porter employed at the Shoreditch Working Men's Club, visited his insurance doctor's surgery, and, after receiving medicine, was advised to go home to bed. He called at the surgery six days later; he was visited at home by his doctor, who then sent him to St. Leonard's Hospital, where he died on the following day. Dr. Smith's reported remarks are as follows:—"One feels that he ought to have been recognised as being a very sick man. There is far too much of this sort of thing—'Go home and let me know how you are getting on.' Speaking generally, the home treatment of panel patients who are not well enough to go to the surgery is very inadequate. Too often it is a case of '*Go home and come back again when you are better.*' If in the interval the man gets worse and dies, a death certificate is issued and nobody hears of the case."

Dr. C. L. Batteson, secretary of the London Panel Committee, who was present at the inquest, remarked that *to say that the home treatment was inadequate* was a sweeping statement. He asked whether the coroner intended it to apply generally, or only to this particular case. Dr. Smith replied that there were many cases which did not come to the surface where patients were sent home with the message: "Come and see me again when you are better." What the exact percentage of the cases was in proportion to those who had adequate treatment, he was not prepared to say. Later on he added: "I want to be fair, I will modify my statement that, speaking generally, they do not get adequate home treatment . . . But too many of the cases are not followed up at home, and the patient is allowed to muddle along."

We have now received from Dr. Batteson a copy of a resolution passed by the London Panel Committee at its meeting on April 23rd:—

> "That the Panel Committee for the County of London learns with regret the remarks passed by Dr. Edwin Smith at a recent inquest with regard to home attention given to insurance patients in general, and is of the opinion that the coroner had not in his possession any evidence which would warrant such a statement. The Panel Committee considers such unfounded remarks extremely unfortunate as being likely to prejudice the good relations at present existing between insurance practitioners and their patients."

It is presumed that the coroner was speaking of matters which have come under his experience in the particular neighbourhood, and it will be noted that he has already disclaimed any wider application to panel practice in general, but his remarks about the inadequacy of home treatment by insurance practitioners have been given wide publicity, and confidence can only be restored by the knowledge that complaints of this kind are always investigated by the Medical Service Subcommittee of the local Insurance Committee. No doubt this practice will be followed in the present instance.

SYNTHETIC DRUGS.

Mr. Francis H. Carr gave an address on this subject at a meeting of the British Science Guild at the Mansion House, London, on April 24th.

Medical treatment, he said, had become increasingly dependent on the use of substances prepared by chemical synthesis, and to-day in Great Britain the important manufacturing firms were between them making most of the synthetic drugs. The exceptions, which included guaiacol, phenacetin, and veronal, were chiefly substances derived from intermediates employed in the making of dyestuffs, and such substances could be more cheaply produced by the dye manufacturers. The advantages of rationalisation in the fine chemical industry, by interconnecting and rearranging the various branches in order to secure efficiency and the best development, at once became apparent when it was realised that most of the substances manufactured required specialised plant and accumulated experience.

Future progress lay in extending the use of science, in the first place by promoting research in industrial laboratories in the closest possible relationship with that carried out in academic institutions and under the ægis of the Medical Research Council; and, secondly, by finding employment for greater numbers of scientifically trained staffs and workers to whom was given responsibility and a living interest in the work they were performing. Fortunately there had been a great increase during the past decade in the number of men receiving university training in chemical science It was also of great importance that youngsters on leaving *secondary schools at the present day had had sufficient* grounding in elementary science to discover if they had an aptitude for it. These youths on entering industrial laboratories in the chemical industry received some sort of tutelage and practical training by day, and they supplemented this by attending technical colleges by night. In this way a rank and file of able workers was being produced and many new opportunities were opening out for them.

A NEW SIGN OF MEASLES.

Dr. Géza Petényi, lecturer in the University of Budapest, has recently described in the *Orvosi Hetilap* a manifestation of measles which, he says, has not been mentioned hitherto in medical literature. It consists of small dot-like hæmorrhages which appear in the prodromal stage on the buccal mucous membrane at about the same place where the Koplik spots develop, and also on the soft palate. The number of hæmorrhagic dots on the buccal mucous membrane is small, from three to eight; on the soft palate are usually more, in one case 20. The dots develop from one to three days before the Koplik spots and last for two or three days. When they present themselves the buccal mucous membrane is still normal, and the punctate hæmorrhages are therefore distinct. Petényi says he has had the chance of observing a good many cases of measles during the incubation period; in about half of them the phenomenon was distinctly visible and always at the same stage of the disease, and in the same clinical form, so that it could not possibly be accidental, and must be regarded as a regular attendant phenomenon of measles. He does not want to draw any far-reaching conclusions about the symptom. On the one hand, it occurs in the earliest stage of the disease; on the other hand, hæmorrhages in the buccal mucous membrane may be provoked by different processes. Not even Koplik spots make it quite certain that the case is one of measles. Why these dot-like hæmorrhages should be seen in about half of the cases, and not always, Petényi cannot explain; just as, he says, we do not know why in certain cases the Koplik spots or the pre-exanthem are conspicuous by their absence.

THE PRICE OF INSULIN.

THE British Drug Houses, Ltd., and Allen and Hanburys, Ltd., announce that the price of "A.B." Insulin is to be reduced from 2*s.* 8*d.* to 2*s.* as from next Friday, May 10th.

X.Y.Z.—Dr. Horsley Gantt's translation of Pavlov's papers on Conditioned Reflexes, to which a leading article was devoted two weeks ago, is published by Martin Lawrence, 26, Bedford-row, London, W.C.1, at 18*s.*

THE Burroughs Wellcome & Co. West End Exhibition Rooms have been transferred from 54, Wigmore-street, London, W.1, to larger premises at 10, Henrietta-street, Cavendish-square, London, W.1.

Oliver-Sharpey Lectures

ON THE

PHYSIOLOGICAL ANALYSIS OF SOME CLINICALLY OBSERVED DISORDERS OF MOVEMENT.

Delivered before the Royal College of Physicians of London

BY F. M. R. WALSHE, M.D., D.SC. LOND.,
FELLOW OF THE COLLEGE; PHYSICIAN-IN-CHARGE OF THE NEUROLOGICAL DEPARTMENT, UNIVERSITY COLLEGE HOSPITAL, AND PHYSICIAN TO OUT-PATIENTS, THE NATIONAL HOSPITAL, QUEEN-SQUARE.

LECTURE I.

(Delivered on April 30th, 1929.)

IT is characteristic of disease of the nervous system that it shows itself by disorders of function in non-nervous tissues innervated by this system rather than by those local manifestations that accompany disease of other organs and tissues in the body. Therefore an important part of the task of the neurologist is to localise the disease process in the nervous system by the analysis of disorders remote from it. Since within the nervous system there is a degree of local differentiation of function unparalleled in any other tissue, clinical neurology is more essentially the study of applied anatomy and physiology than is any other branch of clinical medicine.

It is on this account that the neurologist finds his most fascinating problems in the physiological interpretation of the symptoms of structural nervous disease; in other words, in the endeavour to deduce the normal functions of the various parts of the nervous system from an analysis of the disorders in function produced by disease.

THE NATURE OF THE PROBLEM.

In dealing with the problem thus stated, neurological thought is largely influenced by certain well-known abstract generalisations. Some of these have proved weapons of the greatest value, but a common tendency to invest them with the quality of dogmas has too frequently led to a subordination of the facts of observation to the exigencies of theory, and to a corresponding neglect of that rigorous correlation of clinical and experimental observation that is essential to a truly physiological analysis of symptoms.

Hughlings Jackson's Theory.

There can be no better illustration of the double-edged quality of the abstract conception, when applied to the interpretation of symptoms, than is provided by Hughlings Jackson's theory of the evolution and dissolution of function within the nervous system. This conception, formulated before this College in his Croonian Lectures of 1884 by Jackson[3] has been widely adopted as a guiding principle in the interpretation of nervous symptoms, and often with the most striking results. Yet from the facts that the various papers in which Jackson developed his views are for the most part hidden in the bound volumes of extinct medical journals, and that no modern and complete restatement of these views has been attempted, many of those who adopt them know no more of them than is contained in those fragmentary and often misleading citations that are passed on from writer to writer. This fact, and the abstract nature of the conception in question, have made its application to the complex problems of clinical neurology no easy matter, while its misapplication has proved a stumbling-block to many seekers after knowledge. An excellent illustration of these difficulties is provided by the oft-quoted statement that "tremor is rigidity spread out thin." The phrase has become a shibboleth that all who approach a consideration of the relationship of tremor to rigidity must fain utter, though to do so paralyses clear thinking on the subject, since the distinction between tremor and rigidity is clearly one of kind and not one of degree.

Further, even for those who are not led captive by an aphorism, there remain pitfalls in the application of Jackson's hypothesis. Thus a common source of error has been the assumption that a symptom, be it one of release or of loss of function, represents the opposite of the disordered function. In the case of certain lesions such a simple interpretation may be valid. But in the great majority of brain lesions the assumption leads to a confusion between symptoms and functions that, as von Monakow has insisted, has been one of the most fruitful sources of error in the determination of cerebral functions. A few illustrations from current neurological beliefs will make this clear.

Thus the development of tremor in paralysis agitans has been attributed to the involvement by disease of a hypothetical tremor-inhibiting centre, the fatigue shown by the subject of cerebellar ataxy to the loss of a reinforcing action of the cerebellum upon muscular contraction; while the tendency of such a subject to overshoot the mark (dysmetria) is said to indicate the loss of a normal "braking" action of the cerebellum upon the same function.

It is surely obvious that ad hoc interpretations of this order are remote from reality and can tell us nothing, yet to such elaborate lengths have they been carried within recent years in the case of the corpus striatum that their absurdity is at last becoming manifest, and in the inevitable swing-over of opinion most of the imaginary "functions" which have been bestowed upon the basal ganglia with such artificial precision are now being denied to them.

The Appeal to Phylogenesis.

Secondly, there is the appeal to so-called phylogenetic considerations in virtue of which certain release symptoms are alleged to be reversions to forms of nervous activity characteristic of earlier phylogenetic stages in the evolution of the nervous system. These "primitive" reactions are supposed to lie latent beneath an age-long, permanent inhibition, but at the releasing touch of the process of dissolution of function are ready to spring into their pristine activity.

Thus, in the mobile spasm of athetosis we are asked to recognise the tree-climbing activities of our ape-like ancestors,[2] in the flexed posture of the hemiplegic arm the normal resting attitude of the simian forelimb,[6] while according to Rivers[7] protopathic sensibility and the "mass reflex" of spinal man represent the normal sensori-motor endowments of some hypothetical primitive animal.

The fascination of these wanderings into the realms of fantasy probably lies in the fact that phylogenetic speculations are as difficult of refutation as they are incapable of proof.

> "It is easy," as Karl Pearson remarks in his 'Grammar of Science,' "to replace ignorance by hypothesis, and because only the attainment of real knowledge can in many cases demonstrate the falseness of hypothesis, it has come about that many worthy and otherwise excellent persons assert an hypothesis to be true because science has not yet by positive knowledge demonstrated its falsehood."

All that has been learned from the actual observation[5] of the elementary nervous system in the lowest forms of animal life to possess differentiated nervous tissues shows it to be an instrument of precision from its first appearance and to be entirely lacking in those "elements of vagueness and confusion" postulated by Rivers for his figment the protopathic animal. Nor has the less profoundly remote reference to our ape-like ancestors any internal corroboration. We shall consider later the view that the spasticity of hemiplegia is a form of hypertonus physiologically related to Sherrington's decerebrate rigidity. In the latter condition both fore and hind limbs are in rigid extension, while in man the spastic arm lies flexed. With the factors determining this anomaly I hope to deal later, but it has been suggested that this flexed posture represents the normal resting position of the simian forelimb, to which the human arm reverts on release from cortical control.

Of the extremely unreal character of this hypothesis we may gain a glimpse from the behaviour of the decerebrate sloth. This member of the Edentata differs profoundly in its mode of life from its immediate relatives in the animal world, and indeed from all other mammals before and after it in the evolutionary scale, in that its life is exclusively arboreal. The sloth spends its life in the supine attitude suspended by its flexed limbs from the branches of trees. Placed on the ground it is helpless. According to Richter and Bartemeier [6] "it is scarcely able to raise its body from the ground and literally has to drag itself along."

If reversion to type, or to prototype, were characteristic of the release symptom surely the decerebrate sloth should become rigid in extension and display the unmasked elements of a locomotor activity more in consonance with that of the order to which it belongs, and that of the forbears from which it has come. Yet the decerebrate sloth is rigid in flexion and continues to hang reflexly from the bough.

This naïve form of appeal to phylogenesis, then, has nothing in common with what was understood by Jackson in his conception of "internal evolution," and is, indeed, nothing but a revival of a mode of thought that dominated medicine in Germany in the early days of last century. In his book "Nosography in Modern Internal Medicine," Faber, in referring to this period, observes that—

> "Karl Hoffmann, influenced by certain ideas in Schelling's 'Naturphilosophie,' described in his 'Ideal Pathology' the various morbid conditions as a kind of retrogression to lower stages of evolution. Rickets signified a return to the mollusca because the bones became soft. He thought individuals suffering from certain digestive disorders had descended to the rank of cattle. That the tongue got white, the urine sedimented, and eructation and vomiting occurred—all indicated a tendency to rumination. A finer example of false analogy can hardly be adduced."

It is apparent, therefore, that our employment as guiding principles of abstract generalisations must constantly be controlled by careful reference to the progressively increasing body of observed phenomena. We must not hesitate to modify or to reject whatever will not stand this reference. We pay but lip service to the masters of a past generation when we exalt their lightest epigrams into axioms that none dare question, and their generalisations into fundamental truths by which all new facts of observation must be assessed.

If we look back upon the past 50 years of neurology in this country we see that the period opened with a close and brilliant association between clinical and experimental investigation, an association maintained for many years and depending upon the fact that clinical and experimental methods were often pursued by the same investigator. Ferrier, Horsley, Beevor, Page May, and Risien Russell were among the outstanding examples of this fruitful combination. Within recent years the collaboration between these two methods has been less close. The hewing out of the main features of neurophysiology by relatively simple experimental methods has given place to the minute analysis of fundamental nervous processes by methods of great complexity. Clinical and pathological problems have become correspondingly difficult and exacting, and a single individual can no longer easily pursue knowledge by all three paths.

Nevertheless, we must admit that the divorce has been most unfavourable to advance by the two latter methods, clinical and pathological, in so far as the *interpretation* of symptoms is concerned. This is illustrated by the barrenness of nearly twenty years of intensive study of the functions of the basal ganglia by these unaided methods. Even in the case of the sensory system, it required the experimental method in the hands of Head and Rivers, Trotter and Davies before the chief factors in cutaneous sensibility could be elucidated. We may say, then, that whatever success has attended clinical studies in the interpretation of the symptoms of nervous disease has been proportional to the degree in which these studies have been inspired by physiological principles, and to the extent to which—within the narrow limits possible in clinical medicine—the precise methods of experimental physiology have been applied.

We may finally attempt to formulate in terms of physiology those aspects of Jackson's theory that are relevant to the specific problems of symptom interpretation that we are to consider.

Three Physiological Levels.

We may distinguish some three physiological levels of function within the nervous system. The *lowest level* is subserved by the afferent and efferent neurones of the segmental nervous system. It is fully organised from birth and has a well-defined range of activities which are not capable either of variation or of amplification during life. On this level is achieved the simple coördination of muscular movement; coördination *by* reflex action and a higher grade of coördination *of* reflex reactions. These reactions include the spinal phasic reactions, and the stretch reflex which is the basis of posture, and also various tonic and phasic reactions described by Magnus and de Kleijn which have their centres in the brain-stem. In short, the function of this level is the coördination of movement and posture.

The *middle level* comprises anatomically the projection system neurones of the cerebral cortex, and possibly those of the basal ganglia. These secure a re-representation of the activities already enumerated, but a more highly differentiated and integrated representation. The function of this level has been shown by Sherrington and Grunbaum to consist in the analysis, or fractionation, of the relatively large movements subserved as reflex reactions by the lowest level, and the synthesis of numerous fractions into a vast number of combinations and sequences of movements and postures that constitute the normal range of voluntary motor activities of the individual.

Finally, we have the highest level consisting of yet another still more complex and differentiated representation of these activities. Under the guidance of the distance receptors this level achieves the final integration of the organism and its adaptation to its environment, using this term in its broadest sense. The middle and highest levels are incompletely organised, or evolved at birth and are capable of a high grade of evolution, or education, during the life of the individual. This is the process spoken of by Jackson as "internal evolution," to the wide range of which in the human brain man owes the differences between himself and the lower animals. It is to be noted that phylogenetic considerations do not figure in Jackson's hypothesis, though he observes that "evolution starts with 'things given' by inheritance."

The effect of disease is to take this physiological hierarchy of levels to pieces from the top; the most recently acquired, most highly specialised and least deeply impressed elements of function suffering earliest and most severely. Since, when death does not ensue, this process of dissolution is incomplete, the earlier acquired, less highly specialised and most deeply impressed elements of function remain and, released from higher control, proceed to overact and to produce what he speaks of as "positive symptoms." Thus nervous disease has a dual symptomatology, there are functions lost and functions released. In the loss of voluntary movements on the one hand, and in the spasticity, clonus, and associated movements on the other, we have in a case of residual hemiplegia the representatives of these two groups of symptoms.

It is in dealing with disturbances at relatively high levels of nervous activity that we see most clearly exemplified these principles of dissolution of function. On the other hand, loss of function restricted to some single component of relatively low physiological level produces a disturbance of function that affects all levels, higher and lower alike. A striking illustration of this is provided by cerebellar ataxy, a disorder of movement that represents an algebraical summation of the activities of all the components of movement remaining after the falling out of the cerebellar component. In voluntary movement we have the cerebral motor cortex activting an unbalanced lower level mechanism, and the result may be regarded as *a general reaction* on the part of a mutilated motor mechanism, a reaction from which we cannot identify the *individual contributions of each active component*, nor deduce the normal functions of the lost cerebellar component. From simple observation, however careful, it has proved impossible to decide precisely what is lost and what released. The crude interpretations of cerebellar ataxy that still pass muster for essays in physiology in neurological literature are the fruit of a neglect to realise the origin and nature of the general reaction, and result in serious errors in the application of Jackson's hypothesis of dissolution of function.[12]

Of the two specific symptom-complexes now to be considered in detail, one—that of spastic paralysis—is an example of dissolution in which the principle of loss and release of function is illustrated; the second, that of paralysis agitans, on the other hand, will be considered as an example of the general reaction.[7]

Having thus stated the nature of the problem and the method it is proposed to adopt in dealing with it, we may now take these two specific symptom-complexes and attempt such physiological interpretation of them as is possible. We shall also consider the relationship obtaining between the spasticity of the former condition and the muscular rigidity of the latter.

THE SYMPTOM-COMPLEX OF SPASTIC PARALYSIS.

Characteristic examples of this are provided by *spastic residual hemiplegia* and by *spastic paraplegia* in extension. An essential factor in its production is some interference with the functions of the pyramidal system of neurones, which we may assume in man to be the sole cortico-spinal pathway for the production of voluntary movements.

The essential elements *in spastic paralysis* may be summarised as follows: (*a*) There is a selective impairment or loss of voluntary movements. In the case of the limbs, with which I am mainly concerned, the incidence of loss is, in order of severity—in the arm all skilled and isolated movements of the hand and digits, extension of wrist and digits, supination of the forearm, abduction and elevation of the upper arm; in the leg dorsiflexion of foot and toes and flexion at the proximal joints. (*b*) The release phenomena include muscular hypertonus, or spasticity, the so-called "associated movements," and other tonic reactions of labyrinthine and muscular origin, the phenomenon of clonus, increased tendon-jerks, and the appearance of the flexion reflex of the lower limb with its component, the Babinski plantar response. It is with the physiological significance of these release phenomena that I propose chiefly to deal.

1. *Spasticity, or Hypertonus.*

Like the loss of voluntary movements, spasticity has a *selective incidence*. Thus in hemiplegia, in the upper limb it is maximal in the flexors of wrist and digits, the flexors and pronators of the forearm, and the adductors of the upper arm. It is usually absent from the extensors of wrist and digits. In the lower limb it is maximal in the plantar flexors of foot and toes, in the knee extensors, and in the thigh adductors. This distribution of hypertonus results in an attitude *of flexion and adduction* in the arm, and one of extension with (plantar flexion) and adduction in the leg.

The quality of this spasticity is most easily determined in the knee extensors. If, with the patient lying supine, we support the thigh in the left hand *and grasp the leg above the ankle with* the right, we find on attempting to flex the knee that the initial five to ten degrees of flexion can often be carried out without resistance. When this limit is passed the muscle develops tension, and opposes a resistance of varying intensity to further stretching over about another thirty degrees of flexion, when the resistance suddenly melts and disappears. *From* this point flexion can be readily completed. It appears that stretch of quadriceps has set up a tonic contraction, which is in turn inhibited if further stretch be imposed. This is the phenomenon known to clinicians as the "clasp-knife phenomenon" and *is characteristic of spasticity.*

Further, stretch of quadriceps effected in this way is sometimes accompanied by a striking reaction in the quadriceps of the crossed leg in cases of spastic paraplegia in extension. If before carrying out the procedure described above the crossed leg is passively flexed and lightly supported by an assistant, we find that passive stretch of quadriceps is accompanied by shortening in the crossed (and previously stretched) quadriceps, and the flexed leg moves into extension. In other words, stretch and inhibition of tonus in one quadriceps evokes reflex tension and shortening in its fellow. For the moment I will refer to this crossed reaction as Phillipson's reflex and defer its interpretation until later.

2. *Clonus.*

Associated with and due to sudden stretch is the phenomenon of clonus, most readily elicited in the way familiar to clinicians in quadriceps and gastrocnemius-soleus. It is a phenomenon peculiar to the spasticity of pyramidal system lesions. In the leg, clonus is elicitable from extensor (including plantar flexor) muscles and is of common occurrence. In the spastic arm, however, clonus is relatively uncommon and when seen occurs in the wrist flexors. The probable significance of this altered incidence will be discussed later.

Another characteristic feature of spasticity is the readiness with which it may be transiently overset, or inhibited, by intercurrent phasic or movement reflexes of cutaneous origin. Thus, pricking or pinching the skin of the spastic leg or foot over a field of varying extent elicits a rapid and sometimes ample and forceful reflex contraction of the limb *flexors (and dorsiflexors).* *In cases of extreme* extensor spasticity it may be necessary to make use of this flexion reflex to overcome the hypertonus and thus allow of passive flexion of the limb.

3. *Associated Reactions.*

These reactions are more familiar to clinicians under the title of "associated movements." They consist in slowly developing, forceful accesses of hypertonus into certain muscles of the already spastic limbs, the arm more especially, which lead to the adoption of new postures by the limb. They are evoked by such semi-involuntary movements as yawning and stretching, and also by any forceful, sustained voluntary contraction of muscles on the normal side in cases of hemiplegia. Thus, during a yawn the hemiplegic arm slowly rises up in front of the chest, the wrist extends, and the digits extend and fan. This new posture is maintained as long as the yawning movement and dies with it. The common associated reaction on purely voluntary movement is increased flexion and adduction of the arm, with either flexion or extension of the leg. Of considerable importance in the interpretation of these familiar reactions is the manner in which they can be varied in form by reflex influences arising in the labyrinths and in the proprioceptors of the neck muscles.

For example, if the standing hemiplegic subject look straight before him and clench the normal fist, the spastic arm which has been lying adducted and slightly flexed at the elbow moves slowly into increased flexion at elbow, wrist, and digits. If we repeat this procedure, with the patient's head rotated towards the hemiplegic side, the spastic arm now *moves slowly into extension* and abduction, the fist remaining closed. If we repeat the procedure a third time, the patient's head now being rotated away from the hemiplegic side, the spastic arm moves slowly into increased adduction and flexion.

Again, in a proportion of cases of hemiplegia, active rotation of the head towards the hemiplegic side against resistance is sufficient to evoke a slow involuntary extension and abduction of the affected arm, while rotation away from the affected side is followed by slow flexion and adduction. This variation in associated reactions on head rotation, and also the reactions resulting from head rotation alone are modifications in muscle-tone produced reflexly by stimuli arising in the proprioceptors of the neck muscles when the position of the head in relation to the trunk is altered.

Similar modifications may be produced by altering the position of the head in relation to the horizontal plane of space.[11] In this case the otolith organs of the labyrinths are the reflex source of the variations. We see, then, that the spasticity of the hemiplegia may be influenced, and the limbs thereby induced to take up new postures by proprioceptive stimuli arising in the labyrinths, in the neck muscles, and in the limb muscles. We may state at once that these reactions belong to the group of tonic reflexes described by Magnus and de Kleijn in the decerebrate animal.

One other feature of spasticity remains to be mentioned. *It is abolished by posterior root section, and* also by intramuscular injection of novocaine in such strengths as paralyse conduction in the sensory nerves only of the muscles—that is, by de-afferentation of the spastic muscle. It is, therefore, a reflex reaction arising by the stimulation of sensory receptor organs in the muscle itself.

To summarise: the features of spasticity of pyramidal lesions are selective incidence; reaction to sudden stretch by tendon-jerk and clonus; reaction to slight increasing stretch by increasing tension, and to further increase of stretch by inhibition, this degree of stretch often invoking increased tension and shortening in the crossed knee extensor (Phillipson's reflex); the presence of tonic reflexes arising in labyrinths, neck, and limb muscles; and ready inhibition by intercurrent phasic reflexes (e.g., the flexion reflex). One other type of release symptom remains to be considered.

4. *The Flexion and Crossed Extension Reflexes: the Babinski Response.*

The Babinski plantar response may be called the hall-mark of pyramidal system lesions. Examination of this response reveals that it is but an integral part of a general flexion reflex of the limb, which includes flexion at hip and knee and dorsiflexion of feet and toes—more particularly of the hallux. Moreover, in well-developed spastic paresis the receptive field of the reaction includes the skin and deep structures of the foot and distal parts of the lower limb. Further, it may be accompanied by a reflex extension of the crossed leg in cases of paraplegia. If the crossed leg is already lying in full extension this movement is restricted to plantar flexion of the foot and great toe (the "crossed plantar response" of clinical observers), but if it be passively flexed prior to stimulation of the crossed sole the whole limb may move rapidly and powerfully into extension. The detailed description of these two reflexes as they occur in man has been given elsewhere[9] and need not be repeated here. They are amongst the most beautiful examples of release of function known to the clinical observer.

THE INTERPRETATION OF THE SYMPTOM-COMPLEX.

The phenomena thus briefly described fall into two groups. Spasticity with its various modifications under diverse influences belongs to the group of sustained or tonic muscular reactions, whilst the flexion and crossed extension reflexes (with their component Babinski and crossed plantar responses) belong to the group of movement, or phasic, reactions. The physiological relationship between the two last-named reactions and the reflexes of the same name described by Sherrington is so evident that we may at once accept them as expressing the release of these spinal reflexes on the abrogation of cortical control.

Passing now to the consideration of spasticity and its associated phenomena, we find in them also a remarkable resemblance to the tonic reflexes which make their appearance in the decerebrate preparation—that is, in such an animal as the cat, after transection of the brain-stem at the intercollicular plane. The extensor hypertonus which develops after this procedure, and is known as decerebrate rigidity, is now so familiar in its general outlines that no detailed description of it is required here, but we may emphasise that its origin as a proprioceptive reflex which is abolished by de-afferenting the tonic muscle, its selective incidence in a physiological group of the musculature, its modification by labyrinthine and muscular afferent impulses with the production of Magnus and de Kleijn's "righting" and other tonic reflexes, and finally its relations to intercurrent phasic reflexes are features which we have found in pyramidal spasticity in man.

A somewhat closer examination of certain features of decerebrate rigidity is necessary to establish more completely the physiological identity of these two *groups of phenomena, animal and human.*

The first of these is the *nature of the stimulus*, which provokes the tonic muscular response. We have seen that in both instances this arises in the muscle itself, the integrity of whose afferent supply is therefore essential. Liddell and Sherrington[4] have shown that stretch applied to the muscle is the normal stimulus. To this the muscle responds by shortening, or, if this be prevented, by the development of tension which persists for as long as stretch is maintained. Muscle tone, therefore, is a stretch reflex.

The nature of the tonic contraction thus set up by afferent impulses in a varying number of stretch receptors in the muscle itself consists in asynchronous contractions of individual muscle-fibres at a relatively slow rate. A sudden series of synchronous afferent impulses, such as may be produced by a tap on the tendon, produces a synchronous volley of efferent impulses from the motor neurones concerned which results in the production of a tendon-jerk, and in certain circumstances in that of clonus.

The relative non-fatigability of the tonic response depends upon the asynchronous nature of the response in the individual muscle-fibres, and upon the fact that the focus of the effector muscle units consists of the relatively slowly contracting, fatigue-resisting red muscle-fibres.

The actual mechanism of the response in the individual fibre is the ordinary one seen in all muscular contractions, and is not a function of sympathetic innervation, but of ventral horn cell activity.

The Lengthening Reaction.

If a muscle already engaged in slight tonic contraction in response to stretch be passively lengthened, its initial response is the development of increased tension, but as lengthening is continued this response is inhibited, the tonic contraction ceases, and the observer who is manipulating the limb feels the resistance of the muscle melt and disappear. At the new and greater length equilibrium between excitation and inhibition is again reached and the muscle resumes its tonic contraction.

The Shortening Reaction.

If the two ends of the tonic muscle be passively approximated, and the muscle allowed to take up a new and shorter length, it is again found to resume tonic contraction at its new and shorter length, and to preserve the new posture thus passively imposed upon it.

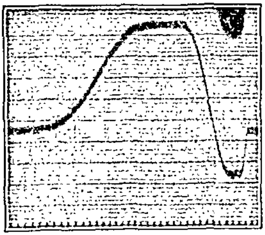
This reaction also is a manifestation of the stretch reflex. For as the muscle is passively shortened the stretch receptors cease to be stimulated, but if the limb be now released its weight tends slightly to stretch the shortened muscle, the stretch receptors are again stimulated, and the tonic response begins again. Even if this release of the limb be not allowed to occur, the stretch receptors adapt themselves to the new length and are again stimulated, the normal anatomical attachments of the muscle providing the necessary tension. Both lengthening and shortening reactions, therefore, are manifestations of stretch reflex activity, and are the basis of the capacity of the limb musculature to maintain a wide range of postures. Denny-Brown[1] has adduced evidence for believing that the tendon organs of Golgi, which are found throughout the muscle in relation with the aponeuroses, are the stretch receptors.

We are now in a position to identify the familiar "clasp-knife" phenomenon, described earlier, as an expression of the lengthening reaction in the spastic muscle. Yet another manifestation of stretch reflex activity in the spastic muscle is the reflex mentioned earlier as Phillipson's reflex. This consists in tonic shortening of one quadriceps when its fellow of the opposite limb is submitted to stretch and shows the lengthening reaction.

The Knee-jerk.

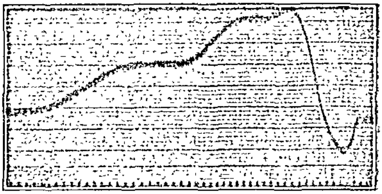
In the spastic limb this reflex presents features which are found to be characteristic of the decerebrate knee-jerk. Pritchard, working with an improved method, in a careful study of the human knee-jerk finds that on the curve of relaxation of the spastic jerk is a "hump," or tonic rebound identical in form and time relationships with that of the decerebrate jerk. (Figs. A and B).

FIG. A.



(A) Graphic record of normal knee-jerk, showing steep ascent, plateau, and uninterrupted descent.

FIG. B.



(B) Graphic record of typical spastic knee-jerk, showing steep ascent, plateau, and "hump" or tonic appendage, on course of relaxation curve.

Both records are to be read from right to left. The initial descent indicates the sudden depression of the patella which constitutes the stretch stimulus. Time-marker strokes shown at the bottom of the figure correspond to 0·01 sec. Both records were obtained by Dr. E. A. Pritchard, to whom I am indebted for them, by a method devised and shortly to be described by him.

Clonus.

In clonus we have another characteristic feature of both spasticity and decerebrate rigidity. It is a response to sudden and maintained stretch, the rhythm of the response being due to alternating predominance of excitation and inhibition.

The Distribution of Hypertonus.

It is in this matter that we meet the only striking difference that obtains between experimentally produced hypertonus and that found in spasticity in man, as we see it in a residual hemiplegia. In the former the incidence of hypertonus is in the extensor of both fore and hind limbs. In man, the leg alone is spastic in extension, the arm invariably becoming spastic in flexion.

Various hypotheses have been put forward by those who accept the physiological identity of decerebrate rigidity and spasticity to account for this difference, but before we can consider them we must discuss the factors which appear to determine the extensor incidence of decerebrate rigidity. Denny-Brown[1] has produced evidence to show that there exist in the limb extensors of the quadruped a large number of effector units (muscle-fibre groups) which have an extremely low threshold of stimulation for the stretch afferents. These low threshold units are composed of the slowly contracting red muscle-fibres. Higher threshold units are composed of more rapidly contracting pale muscle-fibre units. Thus in the complex muscle gastrocnemius-soleus, soleus is a red fibre-muscle, gastrocnemius a pale fibre muscle. A similar division of complex muscles into red and pale muscle-fibre heads is found elsewhere in the body. The low threshold red muscle units form the motor focus of response in the stretch reflex.

Various central influences, such as the labyrinthine and other tonic influences described by Magnus and de Kleijn, still further lower the threshold of excitation of extensor motor neurones, affecting the flexor neurones reciprocally. There exist also in the brainstem, caudal to the intercollicular plane, other sources of predominantly extensor neurone excitation. It is the release of these centres by decerebration, as well as the low stretch-excitation threshold of extensor spinal motor neurones, which determine the extensor distribution of the hypertonus in decerebrate rigidity.

In the limb flexors, on the other hand, there exist comparatively few effector units of low threshold to stretch excitation, and the subsidiary adjuvant sources of excitation mentioned above do not play ordinarily upon the flexor motor neurones. Hence the stretch reflex—that is, tonic contraction—is characteristically a mode of activity of extensor muscles, and there can be no doubt that this functional arrangement is related to the maintenance of the normal quadrupedal posture of standing. We see, therefore, that muscle tone of normal intensity and decerebrate rigidity are essentially the product of spinal neuromuscular mechanism, upon which higher level nervous mechanisms tend to exert a selective and mainly inhibitory influence. Hence release from these higher levels leads to the development of hypertonus.

The Flexed Arm of Hemiplegia.

To account for the flexed arm of hemiplegia we must assume that there has been a functional re-setting of the spinal neuromuscular mechanism, by which the flexor motor neurones have become predominantly responsive to stretch excitation. In the human lower limb we still have a "locomotor prop" whose functions have undergone no alteration with the assumption of the erect posture, and whose extensor motor neurones still remain the chief stretch effectors. On a priori grounds it is not unreasonable to suggest such a functional rearrangement for the human upper limb. It no longer supports the body and an extensor distribution of stretch reflex activity in it has lost its primary purpose. The arm hangs from the shoulder and supports nothing, and in this position the flexors are more constantly submitted to stretch than the extensors. In this connexion it is interesting to note that clonus, one of the most characteristic expressions of stretch reflex activity is a function of limb extensors in the human lower limb, but when found in the spastic arm occurs in the wrist flexors.

We may therefore suppose that the altered relation of the human arm to the postural function has determined a rearrangement of the neuromuscular mechanism of the stretch reflex which is more in consonance with the functions of the arm than an extensor distribution would be. We have seen in the case of the sloth that such a rearrangement has occurred in all four limbs in accordance with their habitual functions, and this in response to the mode of life of the sloth itself and not in relation to its phylogenetic associations.

The interpretation thus developed of the flexed arm in hemiplegia is in accord with physiological principles, has precedent, and does not involve an appeal to phylogenetic analogies. I have earlier referred to the view that the flexed arm represents the resting position of the simian forelimb. Russell Brain[8] who has advanced this view, further states that if the hemiplegic subject leans forward so far that he has to support the trunk to avoid falling—that is, if he mimics a quadrupedal posture—the flexed arm at once goes into strong tonic extension with the forearm pronated and the wrist and digits flexed. In the resemblance which he notes between this attitude and that taken up by the forelimb of the chimpanzee when supporting its trunk on its forelimbs, he identifies an "extensor quadrupedal reflex." He regards the presence of this tonic extension as further proof of his contention that the flexed arm represents the resting position of the chimpanzee's forelimb. Here we seem to have another false analogy. Further, I have never been able to elicit this extensor reflex in the spastic hemiplegic, so that it must be a very rare and inconstant phenomenon. Moreover, in the photographs with which Brain illustrates his argument the subjects presenting extended arms are not in the supported position he describes as essential to its elicitation. We may, therefore, dismiss this hypothesis as unacceptable both clinically and physiologically.

CONCLUSIONS.

From the admittedly brief and incomplete account given of decerebrate rigidity it becomes clear that the spasticity of hemiplegia is physiologically identical with this condition, while for the altered state of the arm reasons have been adduced which do not run counter to known physiological principles and involve no speculative appeals to phylogenesis.

It is, of course, obvious that the condition of hemiplegia is but a fractional expression of decerebrate rigidity, and that a condition approximating to the experimentally produced one must be extremely rare. Nevertheless, a few examples have been recorded in neurological literature and elsewhere[13] I have fully described such a case in which, so far as was clinically possible of verification, all the features of decerebrate rigidity were present in a comatose patient with double hemiplegia resulting from compression of the brain-stem by a tumour. Moreover, it is clear that the release of the spinal reflex mechanism responsible for muscle tone may result from lesions at any anatomical level from cerebral hemispheres to cord, provided that the appropriate descending paths be interrupted. Hence in man we have in spastic paraplegia in extension a condition of extensor hypertonus in the legs presenting the same physiological characters as we find in the spastic leg of the hemiplegic.

In the case of spastic paralysis, therefore, we are able to reach a physiological interpretation of numerous physical signs which cannot be generalised on any other basis than that we have adopted.

JUVENILE BEHAVIOUR DISORDERS IN EPIDEMIC ENCEPHALITIS.

THEIR TREATMENT BY BULBOCAPNINE.

BY T. R. HILL, M.B., M.R.C.P. LOND.,
ASSISTANT MEDICAL OFFICER IN CHARGE OF THE POST-ENCEPHALITIS LETHARGICA UNIT OF THE METROPOLITAN ASYLUMS BOARD, WINCHMORE HILL, LONDON.

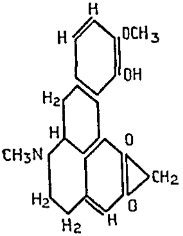
THE disorders of behaviour that so commonly supervene upon an attack of epidemic encephalitis in children have proved up to the present almost completely resistant to any form of treatment. Those suffering from them provide a serious problem both to the parents and to the public health authorities owing to the violent, atrocious, and dangerous forms that their actions take and to the fact that, as their intelligence is so well preserved, it is difficult to place them permanently in institutions.

Failure of Inhibition and its Results.

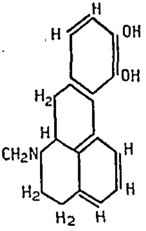
The symptoms are, of course, due to organic disease of the brain and occur usually, and in their most severe forms, in children who are free from parkinsonism or who suffer only from hemiparkinsonism. They are comparatively mild and rare in cases of general parkinsonism. The mental state is one of a loss of inhibition over the primary emotions and—inseparable from these—the innate tendencies towards instinctive behaviour. Thus any stimulus which tends to arouse a primitive instinctive response and the connected emotional state arouses it in these patients to a highly exaggerated extent. For example, the ordinary anger of a normal child when it is thwarted, after the onset of the disease becomes much more violent, prolonged, and easily roused. Because they are so much more instinctive than normal children, they live in continual and restless pursuit of crude emotional gratification, which naturally often takes outrageous forms. They are the slaves of their exaggerated emotions and, though many of them use their intact intelligence to find excuses for themselves, others realise their own state and exhibit distress and repentance. Expressed in popular terms, the marked characteristics of the patients are: pursuit of their own way, impulsiveness, restlessness, lack of self-control, lack of concentration, disobedience, and defiance. Doubtless the reason why after encephalitis this condition appears commonly in children and very rarely in adults is that young people are normally so much more immediately instinctive in their behaviour. The cases are chronic, most of them tending to remain stationary for years, except when parkinsonism supervenes. It will be of interest to observe their progress when they reach a mature adult age, but at present some form of effective treatment is urgently required.

An Attempt to Treat the Symptoms.

As the behaviour disorders are due to organic disease, attempts at psychotherapy are illogical and have proved futile. Drug treatment appeared the most hopeful measure symptomatically, but has hitherto been a complete failure. All the common cerebral depressants, narcotics, and hypnotics, the employment of which seemed naturally indicated, exerted no effect unless given in such large doses as to send the patient to sleep. Recently, however, very encouraging results have been obtained in his hospital by the employment of bulbocapnine. This drug is, according to Gadamer, an alkaloid extracted from *Corydalis cava* (Bulbe creux) and, though its pharmacological action is quite different, it has a chemical structure closely related to that of apomorphine.



BULBOCAPNINE.



APOMORPHINE.

When given to our patients in doses of 0·1 to 0·2 g. three times a day, whether by mouth or hypodermically, it exerted, after two or three days at the most, a marked beneficial action on the mental state and behaviour. This continued as long as the administration of the drug was maintained (a period of about eight weeks' treatment being the longest so far given) except that in some cases a tendency to acquire a tolerance became evident after a few weeks and necessitated an increase of dosage. The beneficial effect at once disappeared on omitting the drug. The absorption was very rapid even when given in sugar-coated tablets by mouth, the first effects appearing as a rule within 30 minutes. Elimination was also very rapid and there was no evidence of a cumulative action. After absorption the first sign was usually drowsiness, and often light sleep, lasting 10 to 30 minutes. This passed off and the patients became normally awake and alert again, but it was then evident that the abnormalities of their mental state and behaviour were markedly diminished. This effect lasted for several hours after the dose. Hyper-affectivity, impulsiveness, and restlessness were much lessened. The patients were not so noisy and defiant, and outbursts of anger, fighting, and interference with their fellows were less severe and frequent. Concentration on school work was much improved in several cases and more ready obedience was displayed. Some of them became practically no more troublesome to look after than normal boys. These doses produced few physical effects in cases free from parkinsonism other than a transient headache, which was complained of by some of the patients during the first day or two of administration. One or two patients appeared to feel the loss of the impulses to behave in their usual way, because for the first three or four days of treatment they complained of not wanting to do anything and sometimes went off naturally to sleep (from which they were easily roused). However, they remained normal and wide-awake during this period if their interest was held by some occupation, and later the complaint and tendency to sleep—except just after the dose—passed away. The syndrome of one case of mild general parkinsonism to whom the drug was given was made worse, the patient becoming more rigid whilst his slight behaviour disorder was little affected.

Except in this last case, which also displayed dystrophia adiposogenitalis, the beneficial effect on the behaviour and mental state occurred in each of seven patients who received bulbocapnine. Brief clinical notes of the six successful cases are given.

Notes of Six Successful Cases.

CASE 1.—Male, aged 12 years, had an acute attack of epidemic encephalitis in April, 1924. Very soon he developed habits of spitting and swearing, was irritable, and was noisy all night. He was admitted to this hospital in March, 1926. He was well-developed, and the only abnormal physical sign was a sluggish pupillary reaction to accommodation. Intelligence was very good and memory fully preserved. There was extreme restlessness and inability to sit or stand still for long. No occupation was persisted in for more than a few moments and any sustained concentration was impossible. He was hopeless in school. Many tics, such as spitting, whistling, and licking his lips, were constantly indulged in, and slight tachypnœa developed in the evenings or when he was excited. He was very impulsive, noisy, and self-assertive, and was always interfering with the other boys, punching them without provocation and for no reason. Any restraint or interference at once led to a violent outburst of temper and assault. He would fight fiercely over the smallest trifles. His condition had remained stationary since admission.

On Jan. 19th, 1929, bulbocapnine treatment was begun in doses of 0·1 g. thrice daily hypodermically; two days later his behaviour was definitely milder and quieter. Immediately after injection he was a little drowsy for 15 to 30 minutes and then normally awake again. On the 24th there was still short drowsiness after each injection, but fighting and temper were much diminished. On Feb. 4th the behaviour of the boy in school was much improved and he was doing better work. He slept for 20 minutes after each injection. On the 15th he showed no temper or restlessness and was as well behaved as any boy in the ward. On the 19th the drug had been omitted for three days; he was much more restless and bad-tempered, and very noisy. The change was very marked.

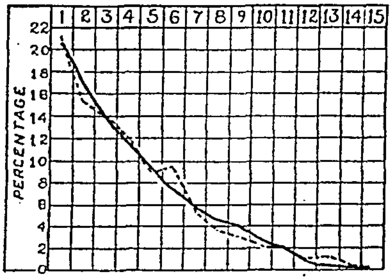
CASE 2.—A boy of 8 had an acute attack of epidemic encephalitis in the autumn of 1924, with a fit and left internal strabismus. A change in behaviour took place immediately afterwards; he threw knives about, swung the cat by its tail, and stole things. There was much nocturnal restlessness. He was admitted to this hospital in December, 1926. He was very small for his age but was otherwise physically normal. Intelligence and memory were good. He was very restless and never sat down or concentrated on anything for more than a few minutes, and was constantly fidgeting and displaying, hopping, licking, and finger-snapping tics. He was impulsive and paid no attention to others, pursuing his own way all the time. He was constantly trying to annoy the other boys by calling them names, and was very disobedient, self-assertive, and talkative. There was an occasional display of over-affection for members of the staff. Petty stealing and consequent lying and much purposeless destructiveness were observed—e.g., he cut away all the ward blind-cords and hid them. Mutual masturbation with another boy was common and he made several attempts to run away. Much temper and fighting took place daily. He was hopeless in school. His condition remained stationary except for day-to-day fluctuations.

Bulbocapnine, 0·1 g. thrice daily hypodermically was commenced on Jan. 25th, 1929, and definite specific improvement in behaviour was observed. Restlessness greatly diminished; instead of chasing noisily round the ward shouting, poking the fires, and destroying things, he sat quietly playing draughts, showed no temper or fighting, and gave no trouble. On Feb. 15th his behaviour was still extremely good—as good as that of anybody in the ward—and he was much less restless. He made no complaints but slept lightly for 20 minutes after each injection.

CASE 3.—A boy of 11 had an acute attack in 1921, when he was drowsy for a short time. This was followed immediately by a change in behaviour. The patient was admitted to this hospital in April, 1928. He was physically normal except for marked polydipsia and polyuria, upon which injections of pituitrin had no effect. His intelligence was excellent, and when he was willing to work he was one of the best boys in the school. There was great general restlessness, impulsiveness, aggression, self-assertion, and desire to have his own way. When obstructed he kicked and stamped with a rage that was described as "terrible." He interfered with the other boys and tried to rob them of any of their possessions that he coveted. This led to quarrels in which he fought with fury. His fighting was often inhibited by fear, and then he vented his anger on himself by banging his head on the wall or hitting himself with a stick for half an hour on end. He was very restless in the evenings, and it was two hours before he settled down to sleep, after running round the ward screaming. He was constantly asking for glasses of water and suffered from nocturnal enuresis. There were frequent exhibitions of pointless destructiveness and marvellous impromptu lying. His condition remained unchanged.

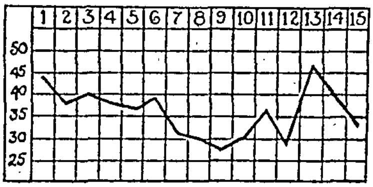
is seen that the same proportion of fourth and seventh children are affected as of first, and that from the ninth child to the last there is a greater percentage of affected than in the first place. This strongly suggests that the first-born is not in such a dangerous position as has been supposed.

FIG. 1.



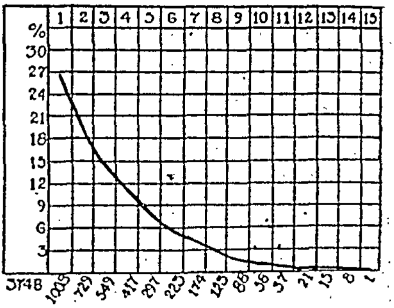
Solid line represents the percentages in each place in the family of 1585 persons, in 286 families, in which there were 600 persons affected with hereditary defects. Broken line represents the percentages of these affected 600 occurring in each place in the family.

FIG. 2.



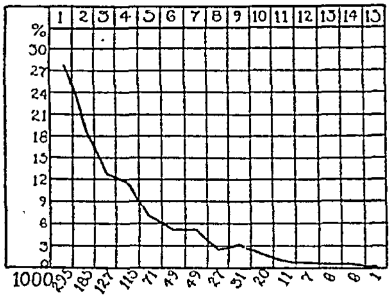
Represents the ratio of affected to unaffected members in each place in family in the 286 families above.

FIG. 3.



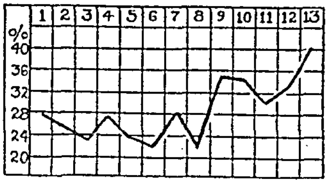
Curve showing percentages occurring in each place in family in 987 families comprised of 3748 members, of whom 1000 showed congenital defects.

FIG. 4.



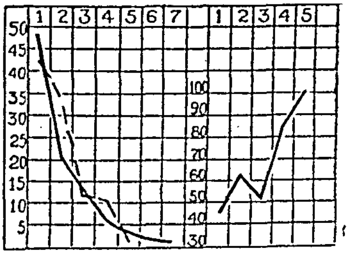
Curve showing percentages of the 1000 affected persons occupying each place in the family.

FIG. 5.



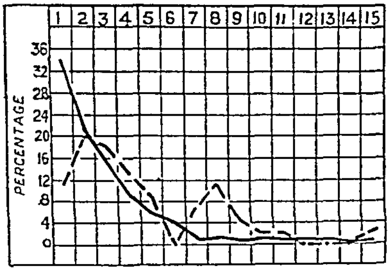
Curve showing the ratio of affected to unaffected members in each place in family in the 987 families listed above.

FIG. 6.



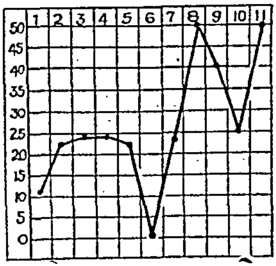
Left side of figure represents in the solid line Still's curve of affected occurring in each place in family based on 400 cases of congenital hypertrophic pyloric stenosis, while the broken line is based upon 59 cases collected by the author. The right side of the figure shows the ratio of affected to unaffected in the 59 families in which the 59 cases occurred.

FIG. 7.



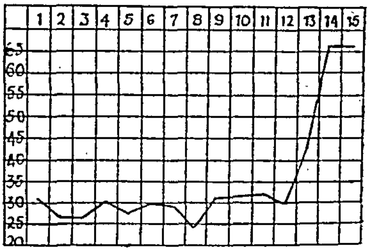
Solid line is Still's curve, showing the percentage of the affected occurring in each place in family in 280 families showing congenital heart disease. Broken line based upon 45 cases collected by the author.

FIG. 8.



Curve showing ratio of affected to unaffected in each place in family in the 45 cases listed above.

FIG. 9.



Curve based upon the combined congenital and hereditary cases listed above, showing the ratio of affected to unaffected in each place in the family.

Still arrives at exactly the opposite conclusion because he plots his curve of place-in-family from statistics based upon a population of which his cases were not a part, assuming that, were his families complete, they would average the same number of children as the population at large. This furnishes a large element of error. In the first place, cases from private practice show a much higher percentage of first-born children than does the population as a whole, since the families are smaller in the wealthier classes. In the second place, the appearance of one malformed child is often the cause of restricting the family, so that there is often no further opportunity for malformed children to be born. Populations differ widely in the number of children in each place in family, and the only safe criterion is the population from which the malformed cases come. Wile and Orgel[2] found that in 1000 families, 28·5 per cent. of the children were the first-born.

Still justifies this method, however, by stating that it makes little difference whether more children are born or not, since his statistics show that seldom is a second defective child born in a family which has already produced one abnormal infant. Here the element of voluntary restriction of the family enters, so that it may be readily understood why a second defective child is not born. In families in which restriction has not been practised or has not been successful, other children with malformations frequently occur. For example, while hunting for 1000 cases in which there was no family history of malformations, I found 64 families in which occurred 167 cases of the congenital type of abnormality usually regarded as non-hereditary. Thus for every 15 families with no familial distribution, there was one family in which there was more than one affected. These two errors, of assuming that the family will produce no more malformed infants once it has produced one, and of plotting his standard curve from a population other than that from which his cases came, lie at the foundation of Still's theory.

---

[2] Wile I. S. and Orgel S. Z.: Internat. Clin., 1928, iii., 145.

The same is true of the particular instances in which Still finds a marked influence of primogeniture, such as congenital hypertrophic pyloric stenosis and congenital heart defects. If we plot our standard curve from the families from which the patients came, there appears no tendency for the first-born to be unduly affected. Fig. 6 give Still's curve based upon 400 cases of pyloric stenosis in the solid line, and mine based upon 59 cases in the broken line. They are sufficiently similar to indicate that the 59 cases were a representative group. In the right-hand side of the figure are the values showing the ratio of affected to normal in the 59 families from which my cases came. Here the first-born is actually the least frequently affected. The same applies to congenital heart defects, although in this case objection might be made that the 45 cases listed in Fig. 7 are not representative, since they do not agree with the curve based on Still's 280 cases (Fig. 7). Picked at random as they were among the group of 1000 cases, they should show some tendency for the first-born to be more often affected if Still's theory were true. Fig. 8, showing the ratio of affected to normal in these 45 families, again shows a lessened tendency on the part of the first-born to exhibit congenital heart defects. When the hereditary and congenital cases are grouped together and the ratio of affected to normal plotted, as in Fig. 9, we see that the first-born in 1600 cases is not more liable to defects than the rest of the family.

It may be objected that congenital defects, usually regarded as non-hereditary, should not be classed with inherited diseases. It is my belief that all developmental defects are inherited, whether there is a family history or not. Some of them may be due to such a complex grouping of determiners in the germ-cells that the chances for more than one child in a family being affected are very remote. On the other hand, there are numerous instances in which such conditions as hydrocephalus, spina bifida, hypertrophic pyloric stenosis or anencephaly are obviously familial, so that we may assume that if they are inherited in one instance they are in all.

The most convincing argument, however, against Still's theory is not the statistical one, since the same numbers will be interpreted differently according to the worker's point of view, but the large number of instances (7 per cent. in the series of 1000 cases) in which the first pregnancy terminated not only in a malformed infant, but in a normal twin as well. If primogeniture be at the basis of the abnormality, why did it not affect both inhabitants of the uterus? The theory of primogeniture falls here, but the explanation that the defects are inherited deals adequately with the situation. How unjust to the parents who have already had the misfortune of bringing into the world one defective child to raise their hopes by false promises! How tragic for them when our promises fail to materialise, and a second malformed baby comes into the world! Although it would be gratifying to be able to assure them that their later offspring will be normal, can we conscientiously do so when we realise that, out of every 16 families in which congenital defects not obviously inherited occur, there will be at least one family, perhaps more, in which there will be more than one defective child? Is it not better to be accurate than to be too hopeful, with disastrous results?

THE MENACE OF APPENDICITIS.

By H. H. GREENWOOD, B.S. Lond., F.R.C.S. Eng.,
CONSULTING SURGEON TO THE GREAT WESTERN RAILWAY HOSPITAL, SWINDON.

It is not possible to estimate, with any approach to exactitude, the yearly incidence of appendicitis on the population; the only figures available are the deaths that result, as recorded in the report of the Registrar-General. Hospital records merely tell us the number of cases admitted to the larger general hospitals, and these bear no constant proportion to the total number.

The pious hope that the insurance card records would furnish accurate returns has been only imperfectly realised. There is no reason to believe that the disease is becoming more frequent, yet the menace of appendicitis, as reflected in the deaths registered, has not diminished since the dawn of the present century. We certainly cannot lay the flattering unction to our souls that the march of knowledge, the more elaborate and widespread equipment of surgical theatres, or a more efficient technique, have in any way diminished the heavy toll of human lives exacted by this eminently curable disease.

For the first four quinquennia of this century, the death-rates per million persons rule 50, 62, 69, 67, and during the ten years, from 1918 to 1927, both the total number of deaths and the death-rate reveal a disquieting increase. It is interesting to compare the rates obtaining for hernia and for intestinal obstruction during the corresponding period (Table I.) in both of which diseases there is a definite decrease in the mortality-rate.

TABLE I.

—	Rate per million persons.	
	1918.	1927.
Intestinal obstruction ..	81	65
Hernia	64	50
Appendicitis	65	70
Total number of deaths	2426	2760

Mr. E. R. Flint,[1] reviewing the deaths from "acute abdomen," at the Leeds General Infirmary, for 1924 and 1925, includes 1080 cases of acute appendicitis with a death-rate of 5·7 per cent. About one-half of these were uncomplicated by abscess or general peritonitis, and of these none died—incidentaly there is no reason why they should—but the remaining half (presumably requiring drainage) seems an unusually large proportion. In my own series only 18 per cent., and in Mr. Grey Turner's series about 26 per cent. were of this severe character. Mr. Grey Turner,[2] in analysing 2252 cases shows, amongst other interesting data, 135 cases uncomplicated by peritonitis, with no deaths; 913 internal operations (also presumably free from peritonitis) with only three deaths, but of 95 cases with diffuse peritonitis 28 (or 29 per cent.) died. The total death-rate for all varieties was only 3·5 per cent. Mr. McNeill Love,[3] in his Hunterian lecture of Feb. 4th, devotes considerable space to a searching analysis of 2018 cases, over a period of five years, and discloses disturbing figures in his table of the results obtained at three large general hospitals—namely, the London, St. Thomas's, and the Manchester Royal. The average total death-rate following immediate operation was 6·7 per cent., rising at St. Thomas's to 8·4 per cent., whilst the average total death-rate following "expectant" treatment was only 3·8 per cent. Regarded superficially these figures should carry conviction, but within them is concealed at least one fairly obvious fallacy. The "immediate" cases include all those definitely perforated or gangrenous cases in which diffuse peritonitis and severe toxæmia are present, and whose mortality-rate in Mr. Grey Turner's series reached the gloomy figure of 29 per cent. These swell the total death-rate of the "immediate" cases, and vitiate comparisons. On the other hand, the deaths under "expectant" treatment (5·7 per cent. at the Manchester Royal, 4·2 per cent. at St. Thomas's, 3·5 per cent. at the London Hospital) occur amongst a group of selected cases, free from any loading by those dangerous, fulminating, and well-nigh hopeless cases in which a fatal termination is imminent. Yet amongst these selected cases, closely watched and nursed with meticulous care, there are 3·8 per cent. of deaths. It is evident that a certain proportion resolve and are operated on as clean cases, none of which should die. The mortality arises presumably amongst those cases which refuse to resolve, marching forward towards disaster and compelling surgical intervention.

It would seem that these must be accounted as errors of surgical judgment since the crucial time for intervention has been deliberately allowed to slip by. The Ochsner treatment has, in many cases, already been adopted before the case comes into hospital and the time for temporising has passed. There are so many factors which conspire to cause a fatal termination—e.g., virulence of the infecting organism, resistive powers of the patient—which cannot be accurately assayed, that one regards with suspicion so dubious a guide as the supposed danger period between the second and the sixth day. The reality of a specially perilous period, between the loss of the natural immunity and the calling-up of the protection conferred by an acquired immunity, is in consonance with the theory of a negative phase, but that this occurs with sufficient certainty between the second and the sixth day, to dictate treatment seems to rest upon too slender a foundation of academic speculation to warrant any deviation from the path outlined by the physical signs. In the race between the rising virulence of the poison and the patient's powers of resistance, the danger period comes to one case within a few hours, to another it may never come at all. There can never be, in any case capable of spontaneous resolution, any period of absolute loss of immunity, else would the patient surely die. During the period of lowered immunity, a period that varies in onset and duration and degree with every patient, the only sure guide is the clinical picture; it is possible that the operation may still be safe during this period provided certain details of technique are adopted. The two cases that came under the observation of Mr. Love (justly stigmatised as "not surgery" by Mr. Grey Turner) were extreme examples, but as regards the operation and the manner of it, it is strange that there seems to be such a lack of agreement amongst surgeons.

Technique of Operation.

The frequent avowal that the gridiron incision is still used at some of our large teaching hospitals is surprising. This incision is eminently suitable only for the removal of a perfectly normal appendix; for a real appendicitis, however mild, the limited exposure of the parts and the inadequacy of drainage when that is necessary—and it can never be with certainty foretold—are amongst the many drawbacks it imposes. It is strange that despite the repeated assaults on its efficiency, this incision has not become completely obsolete. The pararectal incision is similarly, though to a less degree, inadequate. The extent of the opening in the peritoneum is strictly limited by the distance between the nerves entering the outer border of the rectus muscle, and this distance, even in an adult, is rarely more than 2½ in.—a space quite insufficient to allow of the efficient treatment of any but the mildest cases; transgression of these limits incurs the certain penalty of an (incurable) ventral hernia. Rutherford Morison's almost transverse incision, advocated by Mr. Grey Turner, gives excellent exposure, free from the objections inherent in the gridiron incision. Unlike the paramedian incision, however, it cannot be prolonged upwards or downwards, a procedure desirable in certain contingencies, and for this reason I believe that a right paramedian incision at least 5 in., and in stout subjects 6 in. in extent, is to be preferred. In the series recorded here this incision has been invariably used. The right abdominal wall is then pulled well over to the right, large warm swabs shut off the pelvic cavity and cover the small intestines which are then drawn well over to the left. Whenever necessary the cæcum is mobilised along its outer border, a swab placed beneath it to arrest oozing, and the appendix can then be brought nearly to the middle for deliberate removal. Any pus released from a localised abscess is rapidly mopped away and its "bed" made clean and dry. Pus found free in the peritoneal cavity or in the pelvis is usually of a lower virulence than that immediately around the appendix, so that the latter requires careful removal whilst the former will be adequately dealt with by the pelvic drain. In *every* case where a localised abscess is present above the level of the pelvic brim, the "bed" that is left requires a separate drain through a stab puncture internal to the anterior superior iliac spine or through the loin. For the pelvic drain emerging from the lower angle of the wound a double tube is preferable. The pus draining through the stab puncture will be often found to remain virulent and offensive long after that coming from the pelvic drain has ceased or has become innocuous.

The fullest exposure of the parts, careful protection, and gentle handling of the small bowel and ample drainage seem to me vital features in an operation that is undertaken to save life. With full exposure and careful packing, handling of the small intestines is reduced to a minimum.

Experience in a Railway Hospital.

The results shown in Table II., obtained at the Great Western Railway Hospital, of 36 surgical beds which have served a fairly uniform population of 50,000 railway workers and their dependants during the two years April 1st, 1927, to April 1st, 1929, can claim a constancy in all the factors—a stable population, one standard of nursing, a definite technique, and one surgeon.

TABLE II.—*Analysis of 206 Cases of Appendicitis Operated on at the Great Western Railway Hospital, Swindon, between April 1st, 1927, and April 1st, 1929.*

Sex.	Cases.	Age-limits in years.	Cases drained.	Average age.	Deaths.
Males ..	101	$4^{10}/_{12}$ to 63	16	26	0
Females ..	105	$3^{5}/_{12}$,, 62	20	24·2	0

The series of 206 cases may be regarded as average, both as regards severity and age-limits; the rate of flow, about 100 cases per year, seems to be the usual number passing through the hands of any individual surgeon at a large hospital. In one case the appendix was deliberately left, and was removed later; in one case the critical condition of the patient and his age forbade removal, and no further operation has been needed; in all other cases the appendix was removed. A case of left-sided appendicitis with complete transposition of both abdominal and thoracic viscera was merely curious, and cases complicating pregnancy presented no special features of interest, since pregnancy continued undisturbed. The cases requiring drainage were 18 per cent. of the whole and include those in which there was diffuse purulent peritonitis and those cases of localised abscess where the degree of toxæmia indicated a relative virulence of infection; some cases of localised abscess where the pus was of low toxicity and where the "bed" of the appendix could be rendered clean and dry, were closed without drain.

Although the number of cases is comparatively small, I believe that the results obtained by individual surgeons possess a sharper interest and are more free from fallacies than are the deductions drawn from mass statistics. Massive statistics, such as the 2018 cases treated at the London Hospital over a period of five years, may minimise certain inequalities, but they conceal many important factors which defy analysis. These operations are done by various surgeons, with varying views as to clinical signs, with different methods of approach of drainage and of after-treatment, of varying expertness in the technique of dealing with the appendix—a tangle of values from which it is difficult to make safe deductions. The 2252 cases *personally* operated on by Mr. Grey Turner have a more dependable value in that they can claim at least one constant factor—namely, the surgeon. Even these range over a period of 20 years, during which time accumulated experience, increasing dexterity, and modifications of technique would render the data drawn from recent years more representative of an ideal.

It becomes increasingly evident that a reduction in mortality will only be effected by greater precision in diagnosis, earlier operation, a more lively appreciation of the serious nature of the disease, and by a standardisation of technique, especially by the abandonment of those obsolete methods of approach which give too limited an exposure. The present mortality from appendicitis may appropriately be examined in the light of the concluding words of Sir James Berry, in his presidential address to the Royal Society of Medicine, of Nov. 18th, 1920, weighty words that appear have shared the fate of the seed that "fell upon stony ground."

Clinical and Laboratory Notes.

THE TREATMENT OF MIDDLE-EAR SUPPURATION BY IONISATION.

BY J. D. McLAGGAN, F.R.C.S. ENG.,

ASSISTANT SURGEON TO THE LONDON THROAT AND EAR HOSPITAL; ASSISTANT AURAL SURGEON TO THE LONDON COUNTY COUNCIL.

THE following is a critical survey of the results of treatment in 1601 cases of suppurative middle-ear disease in children, with special reference to the method of treatment by ionisation.

The cases were seen at London County Council clinics over a period of three and a half years. Many of them had a discharge so scanty as to be barely perceptible, and required no further treatment than the insufflation of boric powder. Apart from these, all cases were ionised during the first few months, but after a short experience it was recognised that ionisation produced unfavourable results with certain types of ears. Also, owing to the rapidity with which the discharge recurred in children who had enlarged tonsils and adenoids, it became the routine to have these removed as a preliminary measure. If the discharge persisted after the operation, ionisation was carried out. With these exceptions all ears throughout the series were ionised. No selection was made of favourable cases, one of the objects being to find out what proportion of all discharging ears responded to the treatment.

Technique and Results.

The *technique* used was very simple and followed closely the lines advocated by Dr. A. R. Friel and Dr. T. B. Jobson.

The ear was thoroughly cleaned by syringing and mopping, and a small pledget of cotton-wool wrung out in a weak solution of cocaine and adrenalin was introduced into the meatus and allowed to lie in position against the tympanic membrane for three minutes. Thereafter as much pus as possible was sucked out into the meatus by means of Siegel's speculum and the child was instructed to carry out Valsalva's method of inflation so as to clear the Eustachian tube if possible. Then the meatus was again mopped dry. Sometimes the intratympanic tube was used to secure still more complete cleansing. The ionising fluid introduced into the meatus was zinc sulphate, grs. 2 to the ounce. If the perforation in the tympanic membrane was small, Siegel's speculum was used to ensure that the tympanum was filled with the fluid, the air in the cavity being first exhausted. The current used varied from 1 to 3 milliampères and was passed over a period of from 10 to 15 minutes. Afterwards the ear was mopped dry and a small quantity of boric powder insufflated. No further treatment of any kind was given until the ear was inspected a week later. If, at that time, the ear appeared perfectly dry the patient was instructed to report at regular intervals for examination. On the other hand, if the discharge continued but some improvement was noted, the ear was ionised again. *It was very rare for an ear which ultimately benefited* by ionisation not to show a marked improvement after two or three treatments.

Results.—It is always difficult to estimate the value of treatment, especially in a disease which undergoes periods of spontaneous improvement. In the Table I have included under the heading "dry following ionisation" only those cases which were seen to be dry immediately after the treatment, and which were dry at the inspections carried out at intervals of two and three weeks. Moreover, the majority were inspected six months later.

Total number of cases seen	1601
Total number discharged dry	1111
Number of cases ionised	919
Number dry following ionisation	485

Number discharged dry = 69·4 per cent. of total number seen.
Number dry after ionisation = 30·3 per cent. of the total number seen.
Number dry after ionisation = 52·8 per cent. of number of cases ionised.

When a case was discharged "dry" it was explained to the parent that there was still a perforation in the tympanic membrane, and that there was a likelihood of future ear trouble. Great stress was laid on the necessity of bringing the child back if this should occur. In all 101 cases, which had been finally discharged as dry following ionisation, reported with a recurrence of suppuration. This relatively high percentage (20·8) was accounted for mainly by the use of ionisation when there was a predisposing factor to recurrence in the nose or pharynx. The preliminary enucleation of enlarged tonsils and adenoids was a great aid to permanent healing. A notable feature of the ears in which recurrence of the discharge took place was the almost unfailing regularity with which ionisation cleared up the discharge a second time.

Control Cases.

As it had been stated that the success of ionisation was due to the thorough preliminary toilet and not to the ionisation, it was decided to test the truth of this statement. A hundred cases which were judged likely to respond to ionisation were treated by cleansing the ear exactly as for ionisation. Alcohol drops were then introduced and kept in the meatus for 10 minutes, the ear was dried out, and boric powder was insufflated. In no single case was an ear so treated seen to be dry at inspection a week later. In many there was a considerable lessening of the discharge, but none were quite dry.

The Favourable Type of Ear.

After experience had been gained it was not found to be difficult to foretell, with considerable accuracy, whether an ear was going to benefit by ionisation or not. The following points were found to be the chief aids in prognosis :—

1. *Duration of the Discharge.*—In many cases successfully ionised the history of the discharge went back to infancy. A long history was not considered a very unfavourable point, but a long-continuous history was of bad omen. Periods of intermission of several months' duration were favourable.

2. *Character of the Discharge.*—The most favourable type of discharge was the muco-purulent. The least favourable type was the persistently offensive, purulent discharge.

3. *Original Cause of the Onset.*—In the vast majority of the cases the parent was unable to give a definite cause of onset. Very often there was no history even of pain. In those cases which followed measles or scarlet fever the results were much worse than in the majority with no definite history of onset. Of 159 ionised cases which owed their origin to these diseases only 41 responded to the treatment—a percentage of 25·8, which compares badly with the over-all percentage of 52·8.

4. *Examination of the Middle Ear.*—Success was almost entirely limited to those cases in which the infection was confined to the mucous membrane of the middle ear tract, and in which there was no obvious involvement of the underlying bony structures. Thus a favourable examination was one which revealed a perforation through the membrana tensa only, or encroaching on the bony tympanic ring to a very small extent. The mucous membrane of the tympanum, as seen through the perforation, appeared to have its epithelial layer intact. The actual size of the perforation in the membrana tensa was not considered important. Those with a pin-hole perforation responded as well as those with a large one if care were taken to introduce the ionising fluid into the middle ear by the use of Siegel's speculum. An unfavourable finding was the presence of granulations or polypi, which were looked upon as indicating a greater or lesser degree of bone necrosis. Equally unfavourable was a perforation through Shrapnell's membrane or through the outer attic wall. Perforations in this region usually seemed to be associated with cholesteatomata, and no success was obtained in those cases.

5. *Examination of the Nose and Pharynx.*—The presence of enlarged tonsils and adenoids, or other septic foci in the nose and throat, did not prevent the ear from responding to ionisation, but they rendered recurrence frequent and rapid, and should be dealt with before ionisation.

Results in Selected Cases.

During the last six months of the period during which the ears were seen a special group of 21 cases was selected as being especially suitable for ionisation. Of these cases no fewer than 19 dried up and have remained dry until the present time. The large percentage (90·4) of dry ears obtained in this series affords grounds for the statement that, with experience, it was not a difficult matter to foretell with a degree of certainty whether an ear would answer to the treatment or not. These selected cases were not included in the table.

Advantages and Disadvantages.

As stated above, harmful results followed the ionisation of certain ears. The following are contra-indications to ionising :—

1. The presence of acute inflammation. The preliminary syringing appeared in some cases to carry infection to the mastoid antrum and precipitated an attack of acute mastoiditis. There were two cases which lent support to this belief.

2. Marked involvement of the structures in the mastoid process. It was found to be difficult to estimate the degree to which the mastoid process was involved, but ionisation was feared in two classes of cases: first, those which gave a history of recurrent attacks of earache and mastoid pain, the attacks usually coinciding with a short period of cessation of the discharge, and being relieved by its renewed onset; secondly, cases which showed a postero-superior perforation with marked involvement of the bony tympanic ring and in which pus could be freely aspirated from the direction of the aditus.

3. The presence of manifest cholesteatomata.

4. A history of vertigo, with or without the presence of the fistula sign. Apart from the fact that these were usually cases in which there was evident bone necrosis, ionisation readily produced in them an attack of giddiness, often with vomiting.

The *advantages* may be summarised as follows :—

1. The treatment is an easy one for the specialist to apply and takes very little time.

2. After experience had been gained, and the unsuitable type of ear omitted from the treatment, no bad result was obtained.

3. It was found easy to apply the treatment in children as young as four years of age.

4. Ionisation did away with inefficient home treatment and the unsatisfactory cleansing of the ears by drops.

5. Ionisation produced a cessation of the discharges in 30·3 per cent. of all the cases seen. When the cases were carefully selected this percentage was very greatly increased.

In my opinion ionisation, while not by any means solving the problem of the treatment of all chronically discharging ears, is a very valuable therapeutic aid and should be more extensively used by the otologist than it appears to be at present.

THE TREATMENT OF ULCERS OF THE LEG WITH MAGNESIUM SULPHATE.

BY J. H. YOUNG, M.B., CH.B. EDIN.,
LATE JUNIOR RESIDENT MEDICAL OFFICER, CRAIGLOCKHART HOSPITAL, EDINBURGH.

OF all the conditions which cause heartburning in practice, ulcers of the leg are amongst the worst. Many patients go about for years with such lesions, treatment of all kinds having failed. They frequently cause loss of working time.

During the early part of 1928 I had the opportunity of observing the effects of solutions of magnesium sulphate on ulcers of this kind. The successful use of this drug in the treatment of inflammatory conditions has been reported on by Alston,[1] Choksy,[2] and Tucker,[3] but as far as I know, no mention has been made of its employment in the treatment of ulcers of the leg. The observations were made at Craiglockhart Hospital, Edinburgh, a poor-law hospital. Almost every case of ulcer admitted had become callous, and several were of some years' standing. Many had been treated by various remedies without improvement. Without exception, the use of magnesium sulphate solutions improved the condition of affairs, and in over 80 per cent. of cases complete healing resulted.

The patients were all confined to bed with the foot of the bed elevated. Soaks of a 5–10 per cent. solution of magnesium sulphate were applied and the dressing renewed thrice daily. The following case is typical of many.

A married woman, aged 52, was admitted on March 28th, 1928, with an ulcer of several years' duration. It was situated on the left leg and extended from the tuberosity of the tibia to within 3 inches of the ankle-joint. It involved three-quarters of the circumference of the leg, and in the middle third the entire circumference except for one inch. There was a profuse discharge of fœtid pus and the leg was swollen and œdematous. The Wassermann reaction was "marked positive," but on a previous admission to hospital the exhibition of neokharsivan and bismuth over a prolonged period had failed to improve the condition. There were no obvious varicose veins.

Treatment with eusol for 17 days left the condition unchanged. On April 14th, 1928, treatment with 7½ per cent. soaks of magnesium sulphate was begun. The discharge of pus was quickly replaced by one of serum. This appeared to clean up the ulcer and rapid improvement set in. Healthy granulation tissue began to form in the base of the ulcer and epithelium soon started to grow in from the edge. Before commencement of the new treatment the longest diameter of the ulcer, allowing for outlying islets, was 20 cm. Within ten days this was reduced to 15 cm., and by September the lesion was completely healed. She was kept in bed during the greater part of the treatment, but was allowed up for a short time each day during the last month.

A considerable number of similar and varicose ulcers were treated in the same fashion with the excellent results previously mentioned, and I am firmly convinced that as a stimulant to epithelial growth magnesium sulphate stands alone.

It may be of interest to record a case of tuberculous ulcer treated by the same method.

Following a cellulitis of the left leg, a man, aged 56, developed an ulcer on the postero-lateral aspect of the middle third of the left leg. The edges were purple in colour and markedly undermined. The floor was covered by a black slough, and there was a profuse discharge of pus. Such was the state of affairs on April 24th, 1928. Under treatment with 5 per cent. magnesium sulphate solution the slough came away in four days. A portion of tissue from the base of the ulcer was then removed for microscopic examination. The report was as follows: "Sections show the presence of tubercular infection." On May 2nd there was marked improvement. The ulcer was much smaller and actively growing epithelium was present at the edge. Healing continued steadily, and was complete by June 13th. One month later there was a slight recurrence rapidly cured by similar treatment. The patient was still well three months later. A conspicuous feature was the very slight degree of scarring and absence of pain.

I am indebted to Dr. J. W. Keay and Dr. M. M. McGarrity, principal and senior medical officer respectively of Craiglockhart Hospital, for permission to publish these cases.

Medical Societies.

ROYAL SOCIETY OF MEDICINE.

SECTIONS OF SURGERY AND MEDICINE.

A JOINT meeting of these two sections was held on May 1st, Sir HOLBURT WARING, President of the Section of Surgery, in the chair. Dr. HUGH THURSFIELD opened a discussion on the

INDICATIONS FOR AND RESULTS OF SPLENECTOMY.

In this matter, he said, wisdom came but knowledge lingered. The advance of surgical technique had given us in recent years a considerable body of acquired wisdom whilst knowledge of the physiology and pathology remained largely a matter of conjecture and hypothesis. The two undisputed physiological facts were: (1) that the spleen was concerned in the process of digestion, contracting and dilating with the demands of the organism and apparently regulating the supply of blood to the abdominal viscera; (2) that it was enlarged in nearly all acute infections. Every other statement about its function was mere surmise. Other undisputed facts were: (*a*) that the organ recognised as the spleen was seldom if ever the only representative of splenic tissue in the abdominal cavity; splenectomy therefore did not remove all the splenic tissue in the body; (*b*) that the removal of the spleen produced no permanent change which could be constantly identified except that the normal fragility of the red blood cells to saline solutions was definitely and permanently decreased. In particular, splenectomy produced no permanent effect on hæmopoiesis; leucocytosis or leucopenia occurred normally after the operation and the immediate post-operative increase in blood-platelets was temporary only. An enormous practice of splenectomy had grown up during the last 25 years and, although it was based almost entirely on faulty hypothesis, it was fully justified by empirical success.

Indications for Splenectomy.

Splenectomy had become routine practice for at least three diseases: splenic anæmia, congenital acholuric jaundice, and essential thrombopenia. It was possible to recognise a clinical entity called splenic anæmia on the following criteria: chronic cryptogenic primitive splenectomy with no enlargement of lymph glands and the following blood changes: diminution in erythrocytes with absence of erythroblasts, diminution in the hæmoglobin, usually with a colour-index less than 1, diminution in the leucocytes with absence of myelocytes, and diminished or normal fragility of the erythrocytes. Under these conditions splenectomy was indicated as soon as possible and would restore the invalid to decent health, protect him from the almost certain hæmatemesis and possibly cure him. The indications for operation in congenital acholuric jaundice were attacks of anæmia or weakness and the encumbrance of the enlarged spleen. The operation could fairly be said to cure the disease and the fragility of the red cells became normal after a few months. The results of splenectomy were also brilliant in cases of that special type of hæmorrhagic purpura formulated in 1916–17 by Viennese workers and given the name of essential thrombopenia or thrombocytopenic purpura. The restoration of the number of blood-platelets was only transient, but removal of the spleen stopped the hæmorrhages. The operation was indicated by recurrence of severe purpura whether or not the platelets were normal or the spleen clinically enlarged. More than 80 per cent. of cases had been relieved. In acute purpura, however, the figure was only 16·6 per cent., though earlier operation might improve the results. Many workers were abandoning the idea that a thrombocytopenia was a necessary indication for splenectomy.

Among the many other diseases for which the spleen had been removed were acquired hæmolytic jaundice, pernicious anæmia, cirrhosis of the liver, myelocytic leukæmia, and chronic infections such as Egyptian splenomegaly, malaria, tuberculosis, and syphilis. In many cases of acquired hæmolytic jaundice there was extensive disease of the biliary passages, so that simple splenectomy was not likely to give good results. Provided the complication were attended to, 60 per cent. of success had been obtained with splenectomy in the early stages. Strikingly good results had been obtained in pernicious anæmia before the liver treatment obviated operative measures. It had been believed until recently that splenectomy was contra-indicated in cirrhosis of the liver, but if the hepatic function were not too badly impaired, removal of the spleen would bring a cirrhotic process to a standstill, and this measure should be anxiously considered in all early cases.

A Classification of Splenomegalies.

Mr. A. J. WALTON said that the surgeon must evolve a classification upon which to base his views. The diseases causing splenomegaly were so rare that no one surgeon could meet enough cases to give him exact knowledge of the risks and end-results; he must depend on statistics and theoretical considerations. The only common *injuries* were rupture and torsion. Rupture due to direct violence was uncommon and might follow a remarkably slight trauma. The symptoms were those of severe intra-abdominal hæmorrhage and the source of bleeding could seldom be identified. The immediate results of operation had shown steady improvement; the high mortality was due to shock, hæmorrhage, and the other injuries. Removal of the spleen was followed by anæmia, leucocytosis, and lymphocytosis lasting about a year, and then by eosinophilia for about three years. Many had found also an increased resistance of the red cells to hæmolysis, and consequently a reduction in the amount of bile-pigment. The platelets also were increased in number. Spontaneous rupture was nearly always associated with previous splenomegaly and good results had followed operative treatment. Torsion only occurred when the viscus had a relatively long pedicle, which was rare; it was likely to be mistaken for torsion of an ovarian cyst. The results of splenectomy were very good indeed.

Local lesions could be divided into cysts and tumours. The true *cysts* were angiectatic, neoplastic, dermoid, or parasitic, and the false cysts traumatic, inflammatory, or degenerative. All cysts were rare. In countries where hydatid cysts were common splenectomy was by no means the operation of choice, and a mortality of 14·3 per cent. had been recorded in 56 cases. Non-parasitic cysts were more common in men than in women. False cysts might be single or multiple. Nearly all cysts caused a tumour which if large altered the splenic outline and if suppurative caused pain, tenderness, and pyrexia. Most of them were best treated by splenectomy, but a large suppurating adherent cyst might need drainage and marsupialisation. Local removal was not usually satisfactory. *Tumours* of the spleen might be fibroma or fibro-sarcoma from the capsule and trabeculæ, lymphoma or lympho-sarcoma from the lymphoid elements, or angiomata or endotheliomata from the vascular and sinus endothelium. The first group usually caused a localised tumour diagnosed simply as splenomegaly and best treated by splenectomy. Lymphomata were often associated with general lymphoid enlargement, making distinction from Hodgkin's disease very difficult. Splenectomy was likely to be very unsatisfactory if there was general lymphatic enlargement. Great splenomegaly due to enormous enlargement of the Malpighian bodies, with general enlargement of lymphatic glands and a normal blood count constituted a syndrome which should be treated by X rays. The vascular endotheliomata were usually simple tumours, of pathological rather than of clinical interest. Gaucher had originally regarded his disease as an endothelioma, but it had now been removed from this group.

Acute inflammations could be provisionally grouped as localised (or abscess) and diffuse, either septic or specific. In all septic conditions the spleen tended to be large, soft, and flabby, but did not cause any symptoms. Abscess was rare and usually followed a localised necrosis, as in infarct. Drainage might be required for an abscess, but otherwise acute inflammations called for no surgical interference. *Chronic inflammations* occurred in: pyogenic conditions, splenic anæmia, cirrhosis of the liver, Hodgkin's disease, malaria, kala-azar, syphilis, tuberculosis, and secondary polycythæmia. The splenomegaly of chronic pyogenic inflammations might closely simulate that of splenic anæmia and could only be differentiated from it by finding the primary septic focus. It was very difficult to determine what part the spleen played in the clinical picture and secondary changes. A. G. Gibson stated that there might be hyperplasia, reduction of lymphoid elements, and infarcts due to local changes, and believed that embolism of the splenic vein sooner or later produced gross destructive and fibrotic changes in the liver. He believed that all forms of splenic inflammation tended to the destruction of blood-elements in varying degree. Splenectomy would not be suggested for enlargement of the spleen directly dependent on some septic focus. The pathology of *Banti's disease* was not understood, but the satisfactory results of splenectomy were best explained by classing it with the chronic inflammations. It was generally accepted that the disease had three stages: (1) splenomegaly and secondary anæmia which might last for ten years or more, and was generally described as splenic anæmia; (2) gradual enlargement of the liver; and (3) gradual cirrhosis and shrinking of the liver with ascites. There was a secondary anæmia with leucopenia and relative lymphocytosis and repeated hæmorrhages, especially from the stomach. There seemed to be no medical means of treatment; in the second stage operation was very satisfactory. The platelet count might be important even in this group. When there was ascites or jaundice the surgical outlook was not so good, and many died from post-operative gastric bleeding. A. G. Parsons said that if the cirrhosis were not too severe the liver might make a functional recovery. *Von Jaksch's anæmia* had such distinct differences from Banti's disease that it should be regarded as a separate clinical entity. It showed a familial tendency and was confined to the first three years of life. In addition to the splenic enlargement, the secondary anæmia, and the relative lymphocytosis, there was a constant myelæmia, the presence of nucleated red cells, and a tendency to spontaneous recovery. It was often associated with rickets, to which it might be partly due. With a recovery-rate of 65–70 per cent. and no tendency to persist, splenectomy was unnecessary. When it was certain that the spleen was affected before the liver, splenectomy might be useful for cirrhosis, but in common cirrhosis the operation was still in an experimental stage. Whatever the nature of *Hodgkin's disease*, the spleen formed only a small part of a general change and splenectomy was useless. The spleen acted as a storehouse for red blood cells and probably for this reason large numbers of parasites in *malaria*, *kala-azar*, and *syphilis* might find lodgment in it. In tuberculosis the spleen might show multiple miliary tubercles, or the foci in the rest of the body might be small or nearly cured while one or two areas in the spleen progressed to caseating masses. An enlargement of the spleen in children with anæmia should always suggest syphilis; there might be no improvement until the spleen was removed. There was always a risk of a later general infection if the spleen were removed for tuberculosis. Splenectomy in the protozoal and tuberculous group must be regarded as an exceptional measure, only to be carried out when all forms of medical treatment had been tried and it was certain that the spleen was the chief if not the only focus in the body. A secondary *polycythæmia* might occur with chronic non-suppurative thrombophlebitis of the spleen, and had been found in tuberculous children. On the assumption that polycythæmia was secondary to chronic inflammation splenectomy had been practised with success in one case. Primary polycythæmia would probably be classified with general blood disease when more was known about it; there were no indications for splenectomy, for more rather than less splenic tissue was needed to deal with the excess of red cells.

General Blood Diseases.
